Craniofacial surgeons are operating more frequently in recent years in the management of traumatic injury, neoplasia, and syndromic and nonsyndromic craniofacial dysostosis, owing in part to the earthquakes in Haiti and Chile in 2010 that contributed to the need for craniofacial reconstructive procedures.²¹ The incidence of associated craniofacial surgical infections was 14.7% in one study and 8.1% in another, but it varies greatly and may range from 3% to 45%, depending on the number of procedures undertaken during a single anesthesia, surgical duration, and the structures involved.^{10,12} A review published in 2005 demonstrated a rate of 3.2 infections per 100 craniofacial surgical procedures and found that surgical duration longer than 7 hours, closure of skin under tension, use of bovine pericardium, and the presence of more than four surgeons in the operating suite were common risks for development of infection.³¹ Determining when an infection has occurred is difficult. The overall facial appearance of the child may be so altered by the surgical intervention and postoperative swelling that even parents may not recognize that infection has occurred. Diagnostic needle aspiration may be helpful. Because infections tend to be caused by bacteria that reside in the sites through which incisions and osteotomies are performed, the main pathogens are skin, paranasal sinus, and oropharyngeal flora. Each additional site that is surgically violated increases the risk for development of an infection. Infections include cellulitis and dehiscence of the wound, infection of subgaleal fluid, osteomyelitis, focal soft tissue abscesses, epidural abscesses, and septicemia.^{10,30,31} Exposure of harvested bone and use of metal plates, special cements, distraction pin systems, and wires render infection treatment decisions difficult, so follow-up plays a greater role in management of related infections than in management of simple surgical site infections. Routes of antibiotic administration and duration of antibiotic therapy are poorly established. Most procedures have required extensive preoperative planning, and what is done may not be so easily undone. The infectious diseases consultant must be prepared to engage in an ongoing dialogue with the surgeon and the patient's family, determining what can be removed and at what cost, providing objective feedback about the success of the treatment to that point, and declaring, when needed, that a failure of medical therapy has occurred. Stating dogmatically that all devitalized bone and foreign material must be removed will, in all likelihood, cause the surgeon to delay requesting consultation when infectious diseases services are again needed.

PROCEDURES AND INFECTIONS

Some children require palatal reconstruction, others need distraction osteogenesis by mandibular distraction pin device systems for mandibular hypoplasia.¹⁷ Some require advancement of large portions of the face. One less commonly performed procedure to correct midfacial retrusion is the frontofacial monobloc advancement.²³ This procedure involves detachment and advancement of the entire facial bony mask and commonly requires a large frontal craniotomy, the bone from which may be shaped to complete the repair or used as needed to form a suitable foundation to which the advanced monobloc can be secured. Osteotomies are performed along the lower portion of the frontal bone and posteriorly along the roof of the orbits, along the lateral and medial inferior walls of the orbits, and through the zygomatic arches, with subsequent pterygomaxillary disjunction. A frontoethmoidal osteotomy divides the posterior portion of the nasal septum to free the monobloc so that it can be advanced and secured in place by wiring it anteriorly to a slightly fore-tilted strip of frontal bone and stabilizing it laterally with wired-in strips of calvarial bone grafts to bridge gaps in the zygomatic arches. Bone blocks in the pterygomaxillary area help to hold the maxillary

portion forward. The temporary dead space created in the anterior cranial fossa is problematic in some patients.²⁹ This procedure is associated with an inherent risk for developing meningitis, which is associated less frequently with the extracranial procedures described later, although meningitis still may occur.²⁷ An alternative procedure that seeks to avoid entering sinus cavities and the cranium is the subcranial Le Fort III osteotomy.^{13,23} Exposure is provided through a coronal incision with distraction of the soft tissues of the forehead. Osteotomies free part of the medial, lateral, and inferior walls of the orbit and the nasal bridge, and the remainder of the midface bloc is freed by pterygopalatine disjunction and osteotomies of the zygomatic arch and posterior nasal septum. Thus only the midface bloc is brought forward, and interposition grafts, hydroxyapatite, microplates, and wires secure the bloc in the advanced position. As in the frontofacial advancement, split calvarial bone grafts bridge the space in the zygomatic arches. A Le Fort I osteotomy is an isolated maxillary advancement procedure that might additionally be used to change the position of the upper teeth.^{13,16,23}

Some cases of Treacher Collins syndrome require the integral (simultaneous midfacial and mandibular osteotomies).²³ In this complicated procedure requiring a tracheostomy, the midface osteotomies exclude the temporal, lateral walls of the orbits from the advanced bloc. In addition, osteotomies shaped like a C or inverted V through the mandibular rami with placement of the interposition bone grafts and wiring provide advancement of the mandible. Split calvarial bone grafts subsequently reestablish the zygomatic arches.

Reconstructive materials include bone autograft and solvent-treated allograft, titanium plates and mesh,⁸ and alloplasts such as polymethyl methacrylate and hydroxyapatite cements, some of which readily accept bone ingrowth and wires. New materials are in development. In an effort to limit postoperative infection, antibiotics such as tobramycin may be mixed into hydroxyapatite cements, which are released into the surrounding field within the first 24 hours of placement.²⁰

In many instances, infection permeates the entire operative field.¹² Donor bone graft sites may be involved in some instances. Bacteria may infect the wound or soft tissue area, may spread by contiguous extension through cortical bone during long periods of contact, or may extend through osteotomies that have disrupted the integrity of the periosteum and cortical bone barriers. Additionally surgical alteration of the local blood supply to the cranial bones through disruption of medullary channels and removal of the adherent periosteum, as well as the presence of hardware required to secure the bony structures in their new locations, can render infection difficult to treat. Repeated or prolonged hospitalizations for previous surgical procedures may predispose to subsequent postoperative infection with multidrug-resistant bacteria. Attempts to reduce the incidence of infection have made the use of parenteral prophylactic perioperative antibiotic regimens for 2 to 5 days commonplace.

The development of meningitis is a concern with many craniofacial procedures; however, the dura provides a significant barrier to infection when painstaking neurosurgical technique is applied during repair. The presence of a cerebrospinal fluid leak is a predisposing factor, and meningitis may be manifested years after the procedure in the case of a leak.²⁷ No cases of meningitis were identified from a combined report of complications after 567 procedures spanning 6.5 years at Medical City Dallas Hospital and at the Division of Plastic Surgery at the University of Pennsylvania in Philadelphia, primarily for cranial vault remodeling.¹¹ Similarly, meningitis was not identified from an earlier report of 170 transcranial operations spanning 10 years at the South Australian Cranio-Facial Unit in which 53 accidental dural tears occurred and 32 planned dural openings were performed.⁹ Nonetheless meningitis

has been documented to occur in association with a frontal abscess with osteomyelitis, subgaleal fluid infection, contamination of cerebrospinal fluid drains, and monobloc advancement.^{12,27}

As with many procedures, longer operative times result in more infections. Staging of surgeries for complicated problems has helped manage the risk for infection. The Australian group mentioned above documented an average operative time of 10.5 hours for patients in whom a postoperative infection developed, which was 2.5 hours longer than operations on patients in whom an infection did not develop.⁹ Longer and more complicated monobloc advancement procedures have been associated with infection rates as high as 45%,¹² whereas anterior cranial vault remodeling may be associated with infection rates as low as 2.5%.¹¹ The dura encountered during primary craniofacial procedures is manipulated more easily and has better vascularization than does the scarred dura encountered in more complicated and laborious secondary procedures, which are associated with higher rates of infection.^{10,11} Additionally craniofacial postoperative infections develop in infants far less frequently than in adults.^{9,11} Of the common procedures, infection remains a relatively rare complication of the less complicated Le Fort I maxillary osteotomy. In a large review of outcomes of 1000 such procedures, only 1.1% developed abscess or related infection.¹⁴ Infections complicating distraction osteogenesis have been reported to occur in 9.5% of cases; however, osteomyelitis or deep infection requiring removal of instrumentation is less common, occurring in 0.5% to 0.9% of cases.¹⁷

As experience in craniofacial surgery has grown, the reduction in the frequency of infection has been attributed to shortened operative time, attempts to avoid entrance into the contaminated sinus cavities (an easier task in young children, in whom the sinuses often are still poorly developed), and mucosal repair at the end of surgery.²⁷ The mean time to diagnosis of infection is approximately 10 days.¹²

MICROBIOLOGY

Procedures that do not violate the mouth or paranasal sinuses, if infected, are usually infected by skin flora. Organisms causing these infections include flora of the skin such as *Candida albicans*, *Staphylococcus aureus* (both methicillin-susceptible and methicillin-resistant strains), *Staphylococcus epidermidis*, and other coagulase-negative staphylococci, group A β -hemolytic streptococci, and *Propionibacterium acnes*.¹⁹ Resident flora of the oropharynx such as *Bacteroides* spp., *Corynebacterium* spp., and various α -hemolytic streptococci including *Streptococcus pneumoniae*, enterococci, *Morganella morganii*, *Eikenella corrodens*, *Haemophilus influenzae*, and *H. parainfluenzae* can be causative, especially in procedures that invade the sinus cavities. In addition, gram-negative organisms, such as *Pseudomonas aeruginosa*, *Escherichia coli*, *Klebsiella* spp., and *Acinetobacter calcoaceticus* may be involved.^{6,11,31} Infections are often polymicrobial and may involve bacteria that are resistant or multidrug-resistant to antibiotics.¹⁹ The frequency of infection with *Candida* spp. is also high and may rival the frequency of infection with more common bacteria.^{11,29,31}

PREOPERATIVE PREPARATION, INTRAOPERATIVE IRRIGATION, AND PERIOPERATIVE ANTIBIOTIC THERAPY

Because wounds created during craniofacial surgery fall between the clean-contaminated category and the contaminated category,^{6,7} screening for and treating dental caries, periodontal disease, and acute sinusitis is prudent before embarking on procedures involving intraoral incisions and trans-sinus osteotomies.²⁸ Vaccination of undervaccinated or unvaccinated children with pneumococcal vaccines during the planning process may be wise.²⁶ Some surgeons make use of intraoperative antibiotic-containing irrigants to help reduce the incidence of infection. These irrigants may be flushed over the intact cranium after subperiosteal exposure and again before skin closure. Other surgeons prefer to use a solution of one part povidone-iodine to four parts saline for intraoperative irrigation.²⁸ No strong evidence supports any one approach over another for reducing infection.¹²

Continuation of antibiotics beyond the intraoperative period is similar to the approach used in treatment of an open fracture and not very much like antibiotic prophylaxis in the traditional sense. The choice and duration of perioperative antibiotics vary among surgical centers and their surgical teams. Antibiotic regimens may include vancomycin, penicillin, ampicillin-sulbactam, a cephalosporin, clindamycin, or any two of these drugs in combination.^{6,7,11,12,14} Erythromycin or other macrolides or vancomycin are used in penicillin-allergic patients in some centers.¹

The optimal duration of perioperative antibiotic therapy is not clear, but duration at most centers ranges from 1 to 5 days. Higher infection rates occurred in some centers that tried restricting antibiotics to intraoperative use only.¹ Reports from one orthognathic surgical center showed a 10-fold reduction in infection rates with a 5-day antibiotic regimen in comparison with a single-day regimen.² However, recent studies have shown no difference in rates of infection when 1-day versus 5-day or longer durations for perioperative antibiotic prophylaxis was used for most procedures.^{18,19} Longer durations of treatment with postoperative antibiotics may be needed for patients with more heavily contaminated wounds, however, including sinusitis or retained contaminated foreign materials.⁶ Some advocates of a shorter duration of treatment with perioperative antibiotics suggested that longer administration of perioperative antibiotics contributes to infection with gram-negative organisms or may result in infection with more resistant gram-negative bacilli such as *P. aeruginosa* or other pathogens such as *C. albicans*.⁸⁻¹²

EVALUATION

Signs of postoperative craniofacial surgical infection include fever, warmth, tenderness, and erythema and rapid recurrence of swelling.⁵ However, fever is a normal physiologic response to craniofacial surgery, occurring up to 5 days postoperatively.^{10,23} Periorbital swelling may persist for some time and vary with sleeping position. Violaceous discoloration and bruising of the overlying skin are common. Distraction pins may dislodge as the integrity of the bone is compromised by infection.²⁶

Purulent or seropurulent wound drainage may indicate underlying soft tissue and possibly bone infection. Wound drainage, pooling, and lack of wound healing at one location should prompt exploration for undiscovered infection elsewhere.⁵ Laboratory abnormalities may be subtle. Leukocytosis may be present. The erythrocyte sedimentation rate has been shown to peak approximately 5 days after major orthopedic surgery and to decline slowly and irregularly for a period of 3 to 9 weeks, but it provides little diagnostic value initially.^{3,15,25} C-reactive protein (CRP) levels peak within 2 to 3 days but usually normalize within 3 weeks.^{3,15,22,25} Because an abrupt increase in CRP may be indicative of infection, some orthopedic centers monitor CRP levels to assist in early detection of infection after elective procedures such as total joint replacement and spinal surgery.^{15,25} There may be value in following the CRP level in craniofacial patients postoperatively.

Needle aspiration of underlying fluid collections is the best primary means of diagnosing infection, especially if significant residual postoperative swelling has rendered clinical assessment of a particular area difficult. Diagnostic imaging such as computed tomography with contrast enhancement or magnetic resonance imaging may identify occult fluid collections, but diagnosing bone infection, especially in the flat bones of the cranium, is difficult with these modalities. Surgical exploration of suspected areas of infection remains the most helpful method to provide diagnostic information regarding infection.

TREATMENT

Management of infections complicating craniofacial procedures is primarily surgical. Open debridement, inspection and scraping of devitalized and contiguous bone, and copious pressurized saline irrigation may be curative. Removal of all hardware, while desirable, is often impractical. Successful treatment of these infections has been reported in some surgical centers in which the initial bony debridement was limited to areas of visibly apparent osteitis.¹¹ The value of adding

antibiotics to the irrigant is questionable. Some physicians argue that irrigation with povidone-iodine may devitalize tissues that participate in the healing process and should not be used, whereas other physicians avoid using povidone-iodine irrigation because of concern about systemic iodine absorption.¹¹

Placement of several drains prevents accumulation of sequestered focal soft tissue fluid collections. Resolution of drainage and subsequent wound healing can be a sign of cure. Continuous subgaleal flow-through irrigation with saline at a rate of 15 to 30 mL/h (with or without antibiotic additives) is an adjunctive measure instituted by some surgeons.¹¹

In infections acquired during cranioplasty, some patient groups may fare well with attempted preservation of a bone flap with minor surgical debridement and systemic antibiotic therapy. Within a small group of five patients who had undergone craniotomy without a history of previous craniotomy, radiation therapy, or skull base surgery, operative debridement accompanied by culture and susceptibility data-driven systemic antibiotic therapy was successful in treating infection with a mean of 35 ± 20 months of follow-up. Several other patients required second-look operations with more debridement, but they did not require removal of the bone flap and were cured. In the same study, the two other subjects had undergone more extensive craniofacial surgery and had recurrent infection requiring removal of the bone flap at 2 months after presentation in one patient and at 29 months in the other; this finding bears out the concern that contamination of the bone flap can result in persistent, long-standing infection.⁴

For infections that complicate procedures not involving the oropharynx or sinus cavities, an antistaphylococcal antibiotic such as vancomycin, cefazolin, nafcillin, or clindamycin may be an appropriate empirical antibiotic choice pending the results of intraoperative drainage and debridement cultures. A third-generation cephalosporin with or without an aminoglycoside may be considered if the risk for developing an infection with a nosocomial gram-negative pathogen is high because

of prolonged hospitalization or persistent tracheal colonization with gram-negative bacilli such as *Pseudomonas*.^{8,9} or if infection of the central nervous system is suspected or threatens. Infections complicating procedures involving the oropharynx or sinuses often are caused by organisms resistant to the perioperative antibiotic chosen.⁶ Thus it may be reasonable to consider antibiotic therapy with clindamycin or metronidazole when a cephalosporin has been used or treatment with a second- or third-generation cephalosporin or ampicillin-sulbactam when clindamycin has been used prophylactically. Since *C. albicans* and other *Candida* spp. contribute significantly to these infections, initial treatment with fluconazole or other antifungal agents, depending on culture identification and susceptibility patterns, is also recommended, especially if *Candida* is isolated.^{18,19} The duration of antibiotic therapy must be individualized to each case based on the organism and site of infection. A period of 6 weeks of antibiotic therapy has been suggested for patients with craniofacial surgical infections, especially those suspected of having osteomyelitis.²⁴ Long-term oral antibiotic suppression may be appropriate for patients who live long distances from the craniofacial surgery center who cannot be observed closely.

Infections in Burn Patients

Janak A. Patel • Gregory J. Berry • Natalie M. Williams-Bouyer

According to the American Burn Association, approximately 486,000 persons were treated for burns in 2011 in the United States; of these, approximately 40,000 were hospitalized and approximately 3240 died of the burn injury.⁴ Most of the deaths were related to residential fires, and about 75% of the deaths occurred before arrival at the hospital. For those who are hospitalized, mortality rate peaks 20 days after hospital admission.⁸² Improvement in the rate of burn-associated mortality is a direct result of advancement in burn care, comprising developments in fluid resuscitation, wound care, early excision and grafting, nutritional support, infection control, and antimicrobial therapy. The mortality rates and lengths of stay of children with burn injury have been reduced greatly in the past several decades. In the 1960s, the likelihood of survival was only 50% for pediatric patients with burns covering 35% to 44% of the total body surface area (TBSA), and few children with burns covering more than 45% of TBSA survived. The average length of stay was 103 days. In 2011, the LA₅₀ (lethal burn size for 50% of patients) for children younger than 16 years exceeded 90% of TBSA.⁴ The overall mortality rate for children is less than 1%, which is much lower than that of adults, who have mortality rates in the range of 2% to 26%.⁴ At the Shriners Hospital for Children–Galveston, sepsis was found to be the leading cause of death and accounted for 47% of deaths.¹⁵⁴

BURN WOUND

Burn Wound Depth

Burn wounds are categorized by their depth (Fig. 76.1).⁵¹ Accurate assessment of the depth of burn wounds is important in planning the early definitive care of an individual patient. However, the majority of burn wounds are evaluated by clinical examination only. In this respect, laser Doppler imaging is an important advance in noninvasive techniques for predicting burn wound depth.⁷⁸

Superficial-thickness burns consist of epidermal damage only. These wounds are painful and erythematous as a result of local vasodilation. They heal spontaneously, usually without forming scars, within 7 days.

Partial-thickness burns involve superficial portions of the dermis. These wounds are painful and often result in formation of blisters. Healing occurs through epithelial migration from the wound edges, hair follicles, and sebaceous glands. Relatively little scarring occurs, and reepithelialization occurs within 2 weeks. Deep partial-thickness burns are much more serious. The majority of the dermis is destroyed, leaving the bases of the epidermal appendages spared. The nerve endings also are destroyed, rendering the wound insensate. Blisters usually are not present, owing to the thicker formation of eschar. These wounds are

FIG. 76.1 Burn wound depth. (From Greenhalgh D. Wound healing. In: Herndon DN, editor. *Total burn care*. Philadelphia: WB Saunders; 2007: 579.)

treated as full-thickness injuries. Reepithelialization is tenuous and slow. The protracted inflammatory phase often results in excessive deposition of collagen and extensive scarring.

Full-thickness burns involve the entire epidermis, dermis, and the deeper subcutaneous tissues. Healing occurs by contraction and reepithelialization from the edges of the wound. These wounds are insensate and without blistering. Infants and young children have a much thinner dermal layer to their skin resulting in increased propensity for deeper burn injury. Treatment requires excision and skin grafting.

Full-thickness burns can extend into the deep tissue, which includes muscle, bone, and viscera. Treatment is debridement and possible amputation. Closure of these wounds may vary from primary closure after amputation to skin grafting and possibly flap reconstruction.

Cytologic Findings

The effects of extreme heat on the skin lead to cellular and subcellular impairment. The determining factors of how severe a burn will be are the temperature, the length of exposure, and the actual burning agent. Moritz and Henrique showed that the skin is able to withstand temperatures up to 40°C (104°F) for relatively long periods of time before an injury becomes apparent.¹⁰⁵ Increase in temperature leads to cell membrane dysfunction as ion channels are disrupted, resulting in sodium and water intake. As temperatures exceed 45°C (113°F), protein denaturation supersedes the cell's reparative capabilities, and oxygen radicals are liberated. Plasma membrane necrosis has been observed in cells exposed to 45°C for 1 hour. Other cytologic findings in thermal injury include the redistribution of solid and fluid components of the cell nuclei. Imbibition of fluid results in nuclear swelling, rupture of membranes, and pyknosis. As denaturation proceeds, vital cellular metabolic processes are injured. If enzyme activity is decreased to less than 50% of its normal level, cell death occurs. In lesser degrees of enzyme impairment, cell recovery may be possible.

Local Tissue Changes

Local burn injury is classically described by Jackson in three concentric zones. As temperature increases, protein denaturation results in coagulation.⁶⁵ The protein architecture is destroyed and new aberrant macromolecules are formed. The central area of a burn wound is that which is in direct contact with the source of heat. Cell necrosis is complete and is called the *zone of coagulation*. Cellular recovery is impossible, and the severity of injury decreases from the surface to the deeper levels. This zone is called the *burn eschar*. At the peripheral margins of the zone of coagulation, a less injured zone is present. The cells in this *zone of stasis* show direct injury from the heat, but the damage is not lethal. However, blood flow becomes progressively impaired to this area. Ischemia to the already compromised cells may lead to necrosis and conversion to dead eschar. Circulatory impairment occurs via adherence of neutrophils to the vessel wall, deposition of fibrin, formation of platelet microthrombus, vasoconstriction, and endothelial swelling. Heat-compromised erythrocytes lose their ability to deform, and their passage through microvessels is impeded. The circulatory embarrassment may be delayed for up to 24 hours, and the ischemia may progress for up to 48 hours after the burn has occurred. If stasis conditions are minimal, the injury may be halted and cell recovery may occur within 1 week. However, this tissue is fragile and further insults such as infection, hypovolemia, pressure, and overresuscitation can lead to further necrosis. Finally, the *zone of hyperemia* lies peripheral to the zone of stasis. This zone sustains minimal injury and often recovers within 7 to 10 days. Notable vasodilation is caused by potent vasoactive mediators secondary to the inflammatory response. Complete recovery is expected in this zone, barring further trauma or infection.

Burn Inflammation

Many of the just mentioned processes are either part of or result from the inflammatory process. Cellular infiltration, initiated by local inflammatory mediators such as prostanooids and leukotrienes, as well as proinflammatory cytokines from the burn wound, begins with the arrival of neutrophils at 4 to 5 days after the burn, followed by macrophages.¹³³ The neutrophils further mediate damage by releasing oxygen free radicals.⁴⁴ Reestablishment of blood flow in the zone of stasis is yet another setting in which oxygen free radicals are produced, leading to further injury. This phenomenon of ischemia-reperfusion injury occurs as oxygen is restored to the tissues.⁷² Inflammation becomes prominent at 7 to 10 days. Consequently blood flow is maximal at this stage, creating a troublesome and hazardous setting for surgical excision of the eschar. Along with local inflammatory responses, several systemic responses occur with burns of more than 15% of the TBSA.

Inhalation Injury

Burn victims, especially those trapped in enclosed areas, injure the respiratory tract on inhalation of toxic gases from surrounding burning materials. An actual thermal airway injury is quite rare. The upper airway is rather effective in cooling and warming inspired air. Also, air has a very low heat capacity. To cause a direct injury to the airway, the flames must come into direct contact with them. Injury to the oropharynx after inhalation of toxic gases resembles thermal injury elsewhere in the body.¹ Protein denaturation, release of inflammatory mediators, and increased cellular and microvascular permeability all occur, leading to airway edema and consequent obstruction of the airway.

The chemical injury from inhalation of toxic gases can damage the tracheobronchial tree. First, separation of ciliated epithelial cells from the basement membrane occurs.¹² Next, the circulation of blood to the lung, as well as to the bronchial tree, is increased owing to vasodilation. Shortly thereafter, edema is evident. The inflammatory phase is followed by an exudative phase.⁶¹ Furthermore the protein component of this fluid is composed of lung lymph and induces bronchoconstriction. As postburn time increases, fibrin casts are formed from the exudates, resulting in obstruction of the airway. As the epithelium sloughs and formation of fibrin casts increases, susceptibility to infection also increases. Pneumonia leading to sepsis and death are well-known sequelae at this stage. Finally formation of pseudomembranes proceeds and then

squamous metaplasia follows.¹¹⁸ Healing may take weeks to initiate, and permanent damage to the airway (e.g., stenosis and formation of tracheal granulomas) may occur.

INFLAMMATORY AND IMMUNE RESPONSES IN BURNS

Intact human skin is vital for preservation of the host's protection against infection. A combination of impaired local and systemic host defenses and loss of the skin barrier are major factors responsible for the increased susceptibility to infections in patients with burns. The major elements initially contributing to the inflammatory response that occurs after burns are incurred include the plasma proteins, mast cells, tissue macrophages, and systemically recruited neutrophils and monocytes.

Alterations in the host defenses include induction of local and systemic cytokine synthesis, decreased immunoglobulin levels, changes in the concentration and activity of both the classical and alternative complement pathways, reduced levels of circulating plasma fibronectin, depressed serum opsonic activity, and impairment of the macrophages, lymphocytes, neutrophils, and the reticuloendothelial system. However, many mechanisms of immune alterations remain unknown; for example, an association of the volume of blood transfusions with increased mortality rates and infectious episodes in patients with major burns was observed in two reports.^{69,118} The immunologic status of the burn patient has a measurable impact on survival, death, and major morbidity.

The Cytokine Response

After burn injury occurs, numerous cytokines are induced rapidly. Many cytokines correlate with the severity of the burn injury and the prognosis. Studies at Shriners Hospital for Children–Galveston have shown a specific pattern of systemic cytokine responses in children with thermal injury. Compared with unburned healthy children, children with burns covering more than 40% of TBSA had significant increases in serum levels of 15 cytokines and immunoregulatory molecules during the first week after incurring the thermal injury: interleukin-1 β (IL-1 β), IL-2, IL-4, IL-5, IL-6, IL-7, IL-8, IL-10, IL-12p70, IL-13, IL-17, interferon- γ (IFN- γ), monocyte chemoattractant protein-1 (MCP-1), macrophage inflammatory protein-1 α (MIP-1 α), and granulocyte colony-stimulating factor (G-CSF).^{39,82} The amount of granulocyte-macrophage colony-stimulating factor (GM-CSF) was significantly increased during the second week after burn occurred. Within 5 weeks, the serum concentrations of most cytokines decreased, approaching normal levels. In another study of children, serum IL-6, IL-8, IL-10, IL-12p70, IL-13, IFN- γ , tumor necrosis factor- α (TNF- α), MIP-1 β , MCP-1, G-CSF, and GM-CSF values were significantly increased in large burns.^{38,82} In general, there is a clear increase in these cytokines when the affected TBSA is greater than 60% when compared with burns affecting a lesser TBSA.⁸²

A recent multicenter study specifically looked at the predictive value of IL-8 for sepsis and infection following burn injury. This study enrolled 468 pediatric burn patients with burns of greater than 30% TBSA and used IL-8 levels to stratify patients into IL-8 low and high groups. These patients were monitored for IL-8 levels for the first 60 days after injury. Based on the results, IL-8 may be a useful biomarker in pediatric burn patients for monitoring multiorgan failure, infections, sepsis, and mortality.⁸³ Another study also reported that pediatric patients with multiorgan failure had significant increases in serum IL-6, MCP-1, and TNF- α , but these were not predictive of outcome.⁸⁴ TNF- α may be the most important cytokine during acute inflammatory injury of burns because it induces production of C-reactive protein (CRP) and IL-6; migration of and phagocytosis by neutrophils and macrophages; hormone regulatory processes, particularly hypothalamic thermoregulation; and insulin hypersensitivity.

In children with inhalation injury, the serum cytokine studies at enrollment showed significant reduction in level of IL-7 and elevation of IL-12p70 compared with children without inhalation injury.³⁸ However, 5 to 7 days later, the levels were comparable. Host genetic factors also may affect the cytokine response in patients with burns. For example, single nucleotide polymorphisms for TNF- α (–308G), Toll-like receptor 4 (+896G), IL-6 (–174C), and CD14 (–159C) were significantly associated with an increased risk for severe sepsis after burns.⁸

In another study, children with IL-10 (–1082GG) genotype, which is associated with high production of IL-10, were found to have an increased risk for sepsis.¹¹⁹ IL-10 has also been shown to be upregulated in the sera of pediatric burn patients.⁴⁶ Furthermore IL-10 has recently been linked to inhibition of IL-17–producing CD4⁺ T cells (T_H17 cells), leading to a decreased response to *Candida albicans* infection.⁶⁴

Neutrophils

Thermal injury induces neutropenia and myeloid maturation arrest despite elevated G-CSF levels.¹³⁵ The degree of neutropenia correlates with the reduction in bone marrow G-CSF receptor expression. The neutrophils of patients with burns also are functionally altered: the expression of the Fc receptor is decreased, and intracellular killing capacity is depressed (this is a differential suppression, more for some organisms than others) and is accompanied by a brief increase in neutrophil respiratory burst response.¹⁰⁷ Failure of initial alkalization of the phagolysosome and alteration of subsequent kinetics of acidification also occur.¹⁶ This depression of oxygen-independent bactericidal mechanism may impair the capacity of the neutrophil for intracellular killing after a thermal injury occurs. Expression of CD16 (Fc receptor [FcR], Fc immunoglobulin G [IgG] receptor) and CD11 (adhesion molecule) on neutrophils is impaired after a major injury occurs; this reduction appears to be related directly to the appearance of bacteremia or pneumonia.⁶ These changes in expression of adhesion molecules, which is closely related to chemotaxis, may play a part in the failure of delivery of neutrophils in adequate numbers to the local site of a burn. Furthermore a defect is present in actin polymerization in the neutrophils of patients with burns; as a basic mechanism of chemotaxis, it also may contribute to a failure of motility.¹⁴⁷ Neutrophil directional migration has also been shown to be impaired in burn patients compared to healthy individuals.²⁰ The ability of glutamine to increase the bactericidal function of neutrophils against *Staphylococcus aureus* has also been reported in neutrophils isolated from pediatric burn patients.¹¹³

Generation of leukotrienes from the neutrophils of severely burned patients also is impaired and appears to be based on the availability, or lack of availability, of the metabolizable substrate-free arachidonic acid.⁷⁷ Because leukotriene B also is a potent neutrophil chemotactic agent, this impairment may further contribute to the failure of neutrophil function.

Complements

The fluid of the burn blister shows much lower opsonic activity for bacteria such as *Pseudomonas aeruginosa* than the patient's own serum.¹¹⁵ A mild impairment of production of C3 and release by macrophages of burn patients in vitro also occurs. Systemically both the classical and the alternative pathways are depleted, but the alternative pathway is more profoundly perturbed. After the development of bacteremia, additional complement activation and depletion occur.¹⁴⁵

Macrophages

Suppression of the ability of the reticuloendothelial system to take up particulate material was among the original observations of burn immunology made in the 1960s. More recent reports, however, have described the demonstration of a differentially increased uptake of colloid in alveolar macrophages compared with other organs, perhaps indicating alveolar macrophage activation. Macrophages and monocytes appear to be activated in a fashion similar to that of lymphocytes after thermal injury occurs. Activation of macrophages, as measured by the serum neopterin level, is increased after thermal injury occurs.⁷ This activation is confirmed by increased expression of the monocyte cell surface antigens C3b and iC3b.¹⁰³ At the same time, expression of human leukocyte antigen-DR (HLA-DR), HLA-DQ, and HLA-DP by monocytes is reduced, and these class II antigens are obligatory for many cell-mediated immunologic processes, thereby implying that a possible loss of function of monocytes occurs after thermal injury.⁴⁸ Production of C3 by macrophages is suppressed in patients with burns, but the synthetic ability for key cytokines such as IL-6 is increased.¹⁵⁹

Peripheral blood monocytes are superstimulated to produce large amounts of IL-1, leading to exhaustion of the function on monocytes.⁹² Reduced production of IL-1 by monocytes was found in patients with

complicated organ injury, multiorgan failure, and systemic infection. Peripheral blood monocytes from severely burned patients also fail to produce MIP-1 α , which has been shown to play an important role in recruitment and activation of various immune cells during infection.⁷⁹ Blood monocytes of patients with burns produce significantly more IL-10 at 7 to 10 days after burn injury, which correlates significantly with subsequent septic events.⁷⁴

T Lymphocytes and Cell-Mediated Immunity

Early studies of T cells in patients with burns showed a variety of changes: impairment in mitogenic and antigenic responsiveness of lymphocytes, suppression of graft-versus-host reactivity related to the size of the burn, suppression of delayed cutaneous sensitivity tests, and diminution in both numbers of peripheral lymphocytes and concentration of thoracic duct lymphocytes. Whether the failure of T-cell functions is due to an intracellular defect related to thermal injury, the result of “overuse,” or indirectly the result of downregulation by the cytokine cascade or other products of the inflammatory reaction remains controversial. A study has shown that severe burn injury could result in activation and maturation of regulatory T cells leading to immunosuppression.⁶³ The elevation of levels of cytokines produced by regulatory T cells and the activation markers on the surface of these cells correlate with burn size and are higher in those with sepsis than those without. However, among septic patients, the regulatory T-cell parameters in the survival group were markedly lower than those with fatal outcome, suggesting that persistence of a pronounced immunoparalysis induced by regulatory T cells after severe sepsis is associated with poor outcome after burns.

IL-17-producing CD4⁺ T cells (T_H17 cells) have been shown to have an important role in protection from *Candida albicans* infection. A recent study looking at the ability of burn patients to generate T_H17 cells in response to *C. albicans* showed that their generation was impaired in pediatric and adult burn patients, presumably due to T_H17-inhibiting IL-10 produced as a result of burn injury. Since burn patients are quite susceptible to *C. albicans* infection, lack of T_H17 T-cell generation may be one mechanism by which infection occurs.⁶⁴

Analysis of peripheral blood T cells supports the theory that, rather than an absolute reduction in CD4 and an increase in CD8 cells, a redistribution of lymphocyte traffic may occur.¹¹⁶ Suppression in the numbers of the total population of lymphocytes is the only consistent overall change. Furthermore not only does lymphocyte traffic between stores of central lymphocytes and the peripheral blood occur after a thermal injury, but the responsiveness of these populations of lymphocytes also varies according to the site; for example, splenic lymphocytes of experimentally burned animals remain most profoundly depressed in response to antigenic stimulation compared with the peripheral blood and other organs.³⁰ In addition, in peripheral blood, the appearance of “activation” antigens on CD4 and CD8 cells (HLA-DR, IL-2 receptor [IL-2R], and transferrin receptor) is depressed significantly as early as 1 day after burn injury occurs.⁹⁶

Addition of recombinant IL-2 does not appear to reverse the suppression of the appearance of surface markers such as IL-2R in burn patients, although it does not improve the response of natural killer (NK) cells to stimulation.⁴² In experimental preparations, at least some of the observed T-cell suppression can be alleviated by early removal of the burn wound, thereby creating one further argument for promptly closing the burn wound.⁵⁴

B Lymphocytes and Humoral Immunity

The function of B cells after the occurrence of a thermal injury is less well documented than is that of macrophages or T cells. The expression of this major histocompatibility complex is impaired and therefore some diminution of B-cell function can be expected as a result of diminished recognition of antigenic presentation.¹¹¹ Under the influence of stress-induced corticosteroids, the number of circulating B cells is relatively increased compared with T cells in peripheral blood.⁷¹ Spontaneous cytokine (IL-4 and IL-2)-induced expression of the activation antigen CD23 is reduced significantly during the second to fifth week after burn injury occurs.¹³⁰

If the products of B-cell activation, namely, the immunoglobulins, are measured in vivo, the results are somewhat difficult to interpret

because of the increased catabolism of protein and the leakage through the burn wound. Briefly, marked diminution of serum IgG concentration (total and all subclasses) is present; these levels return to normal between 10 and 14 days after the burn injury has occurred. Extremely low levels of IgG on admission (300–400 mg/dL) are predictors of a poor prognosis. One study looking at immunoglobulin levels in pediatric burn patients found that the greatest drops were seen in IgG1 and IgG2 subclasses.¹³⁶ Levels of IgM and IgA appear to be relatively unaffected.

Overall the defective production of immunoglobulin after a thermal injury occurs appears to be a factor of macrophage/lymphocyte interaction rather than a failure of intrinsic activity by B cells.³⁷

BURN WOUND MICROBIOLOGY

A working knowledge of the common flora of burn wounds is essential to appropriately tailor therapy. Pathogens peculiar to thermal injuries are basically no different from the normal flora of the environment. Table 76.1 shows the types of microorganisms found in various body tissues and secretions as either normal flora or as pathogens. However, the organisms causing infections change over the course of burn wound treatment. Gram-positive organisms prevail in the early postburn period and then are replaced by gram-negative bacteria and fungi.³⁵ Many of these organisms produce biofilms in burn wounds. The biofilms consist of organisms surrounded by a matrix consisting of various proteins, polymers, complex carbohydrates, and water. Biofilms are associated with development of antibiotic resistance because antibiotics do not penetrate through the matrix in sufficient concentration. Biofilm formation also inhibits effective local immune response as well as wound healing. Using electron microscopy, Kennedy and colleagues showed that in both ulcerated and escharotomy sites, evidence of biofilm was seen as early as 7 days after injury.⁷⁵ Formation of biofilm is best prevented by early excision and coverage of the wound with topical antimicrobial agents.

The organisms that predominate as causative agents of burn wound infection in any burn treatment facility change over time. For example, at Shriners Hospital for Children–Galveston, from 1989 to 1999, only 42% of children died of sepsis due to multidrug-resistant (MDR) organisms; in 25% of these children, *Pseudomonas* was the responsible organism. From 1999 to 2009, 86% of patients died of sepsis due to MDR organisms, and, in 64% of these children, again the cause was *Pseudomonas* infection. In this latter period, *Acinetobacter* also emerged as a major pathogen of death due to sepsis while the role of *Klebsiella* declined. In more recent years, there has been a further shift in the pathogens, described in the following sections.

Gram-Positive Bacteria

The gram-positive predominance is consistent with the normal inhabitants of the skin before the thermal injury. *Staphylococcus* spp., *Micrococcus* spp., *Streptococcus* spp., *Pediococcus* spp., and *Enterococcus* spp. are gram-positive cocci commonly encountered in burn wounds. Erol and colleagues demonstrated that coagulase-negative *Staphylococcus* and *S. aureus* were the most prevalent isolates in admission cultures, followed by diphtheroids.³⁵ These organisms can be life threatening as invasive infections or simply be locally colonized. The distribution of gram-positive bacteria at Shriners Hospital for Children–Galveston, which receives pediatric burn patients from all over the world, is shown in Table 76.2. In 2011, the gram-positive cocci accounted for 55% of bacterial isolates; however, by 2015, this rate had dropped to 46%. In this latter year, staphylococci were more prevalent (61%) than enterococci (29%). Interestingly the rates of methicillin-resistant *S. aureus* (MRSA) and methicillin-sensitive *S. aureus* (MSSA) isolates were equal in 2011, but, by 2015, the MRSA rates had dropped by two-thirds. This recent downward shift in MRSA rates is in keeping with the overall pattern observed in the United States.

Because of such resistance patterns, Cook stresses the importance of microbial surveillance and epidemiologic studies.²⁵ This approach is thought to reduce the prevalence of MRSA, yet it may be inadequate for eradicating or preventing outbreaks. Minimizing transmission and infection is emphasized. However, Reardon and associates suggest that this process is time-consuming and requires extensive resources for

little gain.¹²² Colonization with MSSA and MRSA in 86 patients was studied and found to have no significant changes on length of stay, number of operations, or mortality between these two organisms. However, the presence of either type of *S. aureus* significantly increased the number of surgical procedures performed and the lengths of stay. Many burn units report frequent colonization of burn patients with toxic shock toxin (TSS-1)–producing strains of staphylococci; however, their presence does not correlate well with increased morbidity or mortality rates.²⁴

In the past, group A β -hemolytic streptococcus frequently was the cause of epidemics in burn units, but it seldom is encountered today because of the frequent empirical use of antibiotics for manipulations of burn wounds. Other β -hemolytic streptococci belonging to groups B, C, E, F, and G can be encountered as well.⁹⁰ Significant infection-control vigilance still is necessary because occasional clusters of outbreaks of group A streptococcal infection continue to be reported.^{51,125} Fortunately group A streptococcus remains uniformly sensitive to penicillins, hence prophylaxis and treatment are easily accomplished.

Although enterococcal infections (*Enterococcus faecalis* and *E. faecium*) account for only 22% of burn wound infections caused by gram-positive bacteria (see Table 76.2), a significant cause for concern is the emergence of vancomycin-resistant *Enterococcus* (VRE) in burn units.^{86,88} Although additional morbidity associated with VRE itself is not clear, when it occurs as a polymicrobial bacteremia, a mortality rate as high as 20% has been noted.⁸⁸

Other gram-positive bacilli include the aerobic *Corynebacterium* spp. and *Listeria* spp., as well as the spore-forming *Bacillus* spp. (aerobe) and *Clostridium* spp. (anaerobe). *Bacillus* spp. and *Clostridium* spp. are associated with burn wounds that have come in contact with contaminated soil. In avascular muscle injuries (e.g., electrical injuries or crush injuries combined with burns), the risk for developing tetanus (from infection with *Clostridium tetani*) is high and has led to the practice of using tetanus immunoprophylaxis and booster vaccines.^{87,132}

Gram-Negative Bacteria

The presence of the gram-negative bacteria in burn wounds is due in part to translocation of the bacteria from the gastrointestinal tract of the patients.⁹ In a study of children with burns at Shriners Hospital for Children–Galveston, patients with large wounds (>50% TBSA) were found to have significantly higher colonization with their fecal gram-negative bacteria than were those with smaller wounds.⁴⁰ *P. aeruginosa*

bacteremia is predicted by isolation of *P. aeruginosa* from another site (wound, urine, or sputum), and the prior nonblood isolates of *P. aeruginosa* can correctly predict the antimicrobial sensitivity pattern in 75% of patients.⁹⁵ At Shriners Hospital for Children–Galveston, gram-negative bacteria accounted for 54% of the total bacterial isolates of wounds in 2015 (see Table 76.2). Indeed, the rates increased from 2011 when it accounted for 48% of total isolates. A significant proportion of these bacteria produce extended spectrum β -lactamase (ESBL) enzyme. *Escherichia coli* and *Klebsiella pneumoniae* are the predominant ESBL-producing bacteria. Bennett and coworkers have shown that infections caused by ESBL-producing *K. pneumoniae* are predictive of death when occurring in older persons.¹⁵

Although the carbohydrate-fermenting Enterobacteriaceae account for 64% of the gram-negative isolates as a whole, *P. aeruginosa* and other nonfermenters are also important in burn patients. Other important gram-negative bacteria include the Enterobacteriaceae such as *E. coli*, *Enterobacter cloacae*, *K. pneumoniae*, and *Serratia marcescens*. Enterobacteriaceae also are encountered as a cause of nosocomial pneumonia in patients with inhalation injury who are on ventilators, and they are a cause of urinary tract infection in patients with indwelling urinary catheters. *Acinetobacter*, an increasingly more common cause of gram-negative infections, has been found more frequently in burn patients with glucose intolerance or preexisting diabetes mellitus⁴¹ and in patients with more severe burns and comorbidities.³

Even without invasive infections, gram-negative bacteria have been implicated in systemic inflammatory diseases, including shock and disseminated intravascular coagulation, secondary to the circulation of bacterial endotoxin from the gut and the burn wound.^{81,93} Often gut decontamination is instituted to reduce the incidence of endotoxin-mediated disease.

Fungi

Until the advent of topical antimicrobial agents and systemic antibiotics, fungal infections were not common developments in patients with burns. The burn wound is the site most commonly infected, although fungemia and dissemination to the respiratory tract in patients on ventilators and to the urinary tract in patients with indwelling catheters are encountered frequently. *Candida* spp. are the most common fungal colonizers of the wound; however, fewer than 20% of patients develop widespread candidiasis. Overall the rate of candidemia in the burn patient population is 3% to 5%, and burn wound invasion has a

TABLE 76.2 Bacteria Isolated From 156 Inpatient Acute Care Pediatric Burn Patients Admitted to Shriners Hospital for Children—Galveston (January 2015–December 2015)

	No. (%) of Isolates
Gram-Positive Organisms	
Coagulase-negative <i>Staphylococcus</i>	131 (37.9)

comparable rate. A study of children with burn injury at Shriners Hospital for Children—Galveston showed that those developing candidemia did so during the first week after the burn and 7 days after excision of burn eschar.²⁹ One hypothesis is that massive burns with immunosuppression are further suppressed by repeated surgical intervention, anesthesia, and perioperative use of broad-spectrum antibiotics, further predisposing these patients to early development of *Candida* septicemia. In one study, the attributable mortality rate with candidemia was 15%.¹⁰⁴ With early recognition of invasion of burn wounds by routine biopsies, wound swabs, and early amphotericin therapy, the mortality rate has been reduced to less than 10% compared with 60% to 90% reported in earlier series.¹³¹

Unlike *Candida*, true fungal infections caused by *Aspergillus*, *Penicillium*, *Rhizopus*, *Mucor*, *Rhizomucor*, *Fusarium*, and *Curvularia* occur early in the hospital course, specifically in those exposed to the spores on the ground or in water at the time the injury occurred. Once colonized, broad nonbranching hyphae extend into subcutaneous tissue and stimulate an inflammatory response. Vascular invasion occurs frequently and often is accompanied by thrombosis and avascular necrosis, which is clinically observed as rapidly advancing dark discolorations of the wound margin. Systemic dissemination occurs with invasion of the vasculature.

Viruses

Linnemann and MacMillan performed a retrospective survey of serum for viral antibodies in pediatric burn patients; 22% had fourfold increases in antibodies to cytomegalovirus (CMV), 8% had increases to herpes simplex virus (HSV) and to Epstein-Barr virus, and 5% had increases in antibodies to varicella zoster virus (VZV).⁹¹ None of the patients had evidence of adenovirus or hepatitis B virus infection. On the basis of these observations, a prospective study of viral infections using both serologic and viral culture techniques was performed. This study showed that CMV infection developed in 33% of the children, HSV infection occurred in 25%, and adenovirus infection was noted in 17%. CMV infections developed in all of the most severely burned children, and both primary and reactivation infections were observed. Most primary CMV infections that develop during treatment for burns are likely to occur from transfusion of blood products. CMV infection typically occurs approximately 1 month after the burn occurs and clinically presents as fever of unknown origin with lymphocytosis; however, it rarely alters the patient's clinical course.²⁸ Kealey and colleagues⁷³ have shown that 56% of burn patients who initially were seropositive for CMV had a fourfold or greater rise in CMV antibodies as evidence of CMV reactivation. These patients tended to be younger, to have a larger burn area, and to have a longer hospital stay. No patient who experienced CMV infection, whether primary or reactivated, had serious complications attributable to CMV. On the basis of these observations, despite the availability of anti-CMV agents such as ganciclovir and valganciclovir, treatment of CMV infection remains controversial.¹²³

Since the screening of blood began, hepatitis C virus (HCV) has been an important risk factor. Coursaget and colleagues screened 45 burn patients for anti-HCV antibodies at the time of burn injury and at more than 6 months after the burn.²⁶ HCV infection was detected in 18% of these patients as a consequence of the numerous transfusions of blood or blood derivatives used during the postburn treatment. Five patients displayed evidence of anti-C100, anti-C33c, and anticore antibodies together; two patients had only anti-C100 and anti-C33c antibodies, and the last patient showed only anticore antibodies. Chronic hepatitis was observed in 83% of HCV infections. Kinetics of appearance of anti-HCV antibodies varied among patients. Anticore antibodies generally are the first to be detected at high levels; however, in at least one case, they were detected only 2.5 months after C100 and C33c antibodies were detected. The incidence of HCV using polymerase chain reaction (PCR) assay to detect the viral genome has not been evaluated in burn patients. Nonetheless the current procedures used at blood banks have decreased the transmission of HCV by blood products.

Another transfusion-related agent is human immunodeficiency virus (HIV), which has become extremely rare as a result of the screening of donors that began in 1987 in the United States. However, significant risk existed prior to that period. A retrospective review of children with burn injury at Shriners Hospital for Children—Galveston who had received blood or blood products between 1978 and 1985 identified 52 patients at risk for developing HIV infection.¹²⁷ More than 50% of the identified population had received three or more units of blood or blood products during their acute hospital stay. A total of 214 patients (36.8%) were tested for HIV seroconversions: five tested HIV positive by enzyme-linked immunosorbent assay (ELISA) and four were confirmed by Western blot, yielding a 1.9% incidence. The four confirmed patients received two to nine total-body blood volume turnovers during their postburn period in the hospital. HIV may affect the outcome of burn wound injury. A study of Malawian children showed that with burns affecting 11% to 30% of the body surface area, HIV-positive children had a mortality rate approximately twice that of HIV-negative children.⁶⁶

HSV is of significant concern in burn units because it is a dermatopathologic virus. A review of the literature suggests that patients younger than 10 years were at greater risk for acquiring an HSV infection when the size of the burn wound was greater than 15% TBSA.⁵⁵ However, the role of HSV in the healing of wounds is unclear. Bourdarias and associates showed that, in 11 patients with burns, local areas of active epidermal regeneration were affected most often.¹⁷ Acyclovir therapy was not used, and the duration of hospitalization was normal when compared with that of other children. Nonetheless HSV in lungs may

worsen morbidity. Byers and coworkers showed that the relative risk for developing HSV infection was higher for patients with acute respiratory distress syndrome but not for those with pneumonia.²¹ Disseminated HSV infection also can be fatal.²¹

Another dermatopathologic virus is VZV. Mini-epidemics of VZV have occurred within pediatric burn units.¹⁵³ With the routine VZV vaccination of young children (at 1 year of age) in the United States, outbreaks of varicella in burn units are now uncommon. The characteristic fluid-filled lesions appear in partial-thickness burns that are healed or healing, as well as in uninjured epithelium and mucous membranes. The vesicles are much more destructive in the injured than uninjured skin and may present as hemorrhagic, oozing pock marks that are prone to development of secondary infection and subsequent scarring. Neovascularized skin grafts may be lost; therefore further grafting procedures should be delayed until the lesions are quiescent.

The morbidity due to respiratory virus infections, particularly in those with inhalation injury, has not been studied well. We tested more than 100 pediatric burn patients for respiratory syncytial virus (RSV) during the winter seasons of 1995 and 1996. Only six patients were found to be positive for RSV, with one death (1% mortality rate).

Parasites

Parasitic infestation also is seen, especially in children from the developing world. Because we see many patients who originate from Mexico, where such infestation is endemic, parasitemia has been found to complicate burn injuries. Parasites that are asymptomatic in sites such as the intestinal tract and the respiratory tract can become symptomatic as a result of the stress of a burn injury. At the Shriners Hospital for Children–Galveston, we have described three cases of *Ascaris* pneumonitis that exacerbated smoke-induced lung injury.⁵⁶ In 2006, the parasites isolated most frequently were *Giardia lamblia* and *Blastocystis hominis*.

CLINICAL MANIFESTATIONS

Local Signs

An open burn wound is a favorable target for bacterial colonization. The progression from simple eschar colonization to the invasive process is favored by a series of factors related to the patient, such as extension and depth of the burn, age, presence of previous disease, and local conditions of the wound; to the microorganism, such as density, motility, toxins, and antimicrobial resistance; to iatrogenic causes such as prosthetic devices; and to the nosocomial spread of bacteria. It is essential to recognize the early signs of infection of a local burn wound by examining the wound at least once a day.

The local signs of burn wound infection include black or dark brown focal areas of discoloration, conversion of partial-thickness injury to full-thickness necrosis, hemorrhagic discoloration of subcutaneous tissue, enhanced sloughing of burned tissue or eschar, and purplish discoloration or edema of skin around the margins of the wound. Presence of *Pseudomonas* infection can lead to ecthyma gangrenosa and green pigmentation of subcutaneous fat. In fungal infection, centrifugal advance of subcutaneous edema with central ischemic necrosis and hemorrhagic saponification of subcutaneous fat in fungal infection can be seen. In viral infection, vesicular lesions in healing or healed partial-thickness burns and crusted serrated margins of partial-thickness burns may be observed.

Systemic Signs

Progression from local to systemic invasion can occur rapidly, which correlates with the size of the burn wound, the extent of environmental contamination, and the surgical procedures. Early recognition of systemic invasion is critical to avoid high rates of mortality. Many of the signs of sepsis resemble complications of the burn itself; for example, fevers, tachycardia, shock, and elevated or depressed neutrophil count can occur in burn patients with or without infection. However, certain patterns of clinical signs and symptoms may help identify systemic bacterial invasion (Table 76.3).⁴³

Biomarkers of Infection and Sepsis

A rise in CRP serum levels has been found useful in predicting systemic infection, although increases in the first 2 days after the burn or the

TABLE 76.3 Signs and Symptoms of Progression From Local Invasion to Systemic Illness

Gram-Negative Sepsis	Gram-Positive Sepsis
Burn wound biopsy >10 ⁵ organisms/g tissue and/or histologic tissue invasion	Same
Rapid onset; well to ill in 8 to 12 hours	Gradual
Temperature of 37–39°C (98.6–102.2°F); can be normal, followed by hypothermia (34–35°C [93.2–95°F]), plus decrease in WBC	Temperature >40°C
WBC may be elevated	WBC 20–50 × 10 ³ , hematocrit decrease
Ileus	Same
Decreased blood pressure and urinary output	Same
Wounds develop focal gangrene, satellite lesions away from burn wound	Macerated wounds, ropy and tenacious exudate
Mental obtundation	Anorexic and irrational

Five or more signs or symptoms are definitive diagnostic parameters. Modified from Gallagher JJ, Williams-Bouyer N, Villarreal C, et al. Treatment of infections in burns. In: Herndon DN, ed. *Total Burn Care*. Philadelphia: WB Saunders; 2007:143. WBC, White blood cell count.

day after surgery may occur without infection.¹¹⁰ A recent large-scale study in pediatric burn patients showed that CRP cannot be used to predict infection or sepsis.⁶⁸ Another important biomarker is serum procalcitonin. Its relatively early rise within 4 hours of response to infection or trauma, with a long plateau of up to 24 hours, makes this marker very valuable in early assessment of sepsis. Egea-Guerrero and coworkers showed that procalcitonin levels could predict infection while CRP could not.³³ Furthermore Yang and coworkers showed that procalcitonin levels could predict severity of sepsis as well as mortality.¹⁵⁷ While the serum procalcitonin test is still not yet available widely, many medical centers are increasingly offering this test for routine clinical use. Studies of elevated levels of certain cytokines may also be useful biomarkers of infection, but they largely remain a research tool.

Complications of Infection

Other than the primary infection of the burned skin, several types of infectious complications in burn patients have been recognized. Bacteremia is a frequent complication.

Burn wound manipulations are responsible for development of bacteremias in approximately 50% of cases, but routine instrumentation and intravascular catheter devices also can cause bacteremia.^{14,53} The risk for developing bacteremia also correlates with the TBSA affected by burns; Sasaki and associates showed that those patients with a positive blood culture had an average TBSA injury of 47%, whereas those with a 26% injury had negative blood cultures.¹²⁸ Bloodstream infection has been associated with longer duration of hospitalization and mechanical ventilation but not with mortality.¹⁹ Toxic shock syndrome (TSS) caused by TSS toxin–producing strains of *S. aureus* has been identified in acutely burned children. Childs and coworkers found that 13% of children developed a toxic shock–like illness; however, its effect on overall burn mortality was not clear.²⁴

Subacute bacterial endocarditis is a risk associated with persistent bacteremia of any cause, including repeated instrumentation, surgical intervention, and placement of central venous catheters.^{13,22} *S. aureus* and gram-negative bacilli are the most frequent causes. In most cases, the antemortem diagnosis rarely is suspected in children with burn injury.^{2,15} In addition to causing local valvular damage, infected vegetations may dislodge septic emboli. Suppurative thrombophlebitis occurs at the site of the insertion of the catheter. It may occur in as many as 5% of patients with burns covering 20% TBSA.¹³⁷

Suppurative chondritis occurs in patients with full-thickness burn of the ear.¹⁰¹ Because of the auricle's relatively low level of blood supply, chondritis frequently follows the progression of tissue ischemia, usually 3 to 5 weeks after burn injury occurs.¹⁰² *P. aeruginosa* and *S. aureus* are the most common pathogens. However, with use of mafenide acetate as a topical agent, the incidence of suppurative chondritis has decreased significantly.

Suppurative sinusitis is seen in patients with long-term nasotracheal intubation. In one study, 8% of patients with burns who had nasotracheal intubation for more than 7 days developed sinusitis.¹⁸ Pneumonia may occur with or without inhalation injury, although those with inhalation injury have a substantially higher risk.¹³⁴ Bronchopneumonia is the most common type of pulmonary infection, usually occurring in the second week of burn injury. Predisposing factors are size of the burn wound (hematogenous spread), aspiration, presence of tracheostomy or nasotracheal tube (nosocomial spread from burn wound), existence of inhalation injury, and disturbances of fluid and electrolyte balances. Causative organisms include gram-positive bacteria, especially *S. aureus*; gram-negative organisms such as *P. aeruginosa*, *E. coli*, and *K. pneumoniae*; and viruses, including HSV and CMV. Currently most infection-related deaths in burn patients are caused by pneumonia or bloodstream infections, rather than wound infection.¹³⁴ Fatal viral pneumonia due to CMV and HSV has been described as well.²⁷

Urinary tract infection occurs in association with prolonged and often unnecessary catheterization.¹²⁹ Osteomyelitis can occur when bones are exposed by the burn or by open fracture accompanying the burn; from extension of infection from a septic joint, introduction of organisms along traction pins, and internal fracture fixation devices; or by bacteremia. However, clinically significant osteomyelitis in burn patients is rare.³⁶ Septic arthritis occurs when a joint is exposed by a burn or by removal of burn eschar.³⁶ The joints most frequently exposed are the knee, the elbow, the proximal interphalangeal joints of the hand, and the metacarpophalangeal joints on the dorsal surfaces of the hand. The incidence of septic arthritis is obscured by its frequent association with signs and symptoms of severe burns that rarely are separable. Rarely in burns, a joint may become infected from adjacent metaphyseal osteomyelitis. In children, most joints can be salvaged. Adult joints are less resilient.

Central nervous system infections in burn patients include meningitis, microabscesses, and septic infarcts. In one review, *Candida* spp., *S. aureus*, and *P. aeruginosa* caused almost 80% of infections, occurring most frequently in patients with extensive burns with wound infection or endocarditis.¹⁵⁵

MICROBIOLOGIC INVESTIGATIONS

The three major approaches to determine burn wound infection are (1) quantitative burn wound cultures, (2) histologic assessment of bacterial invasion, and (3) bronchoalveolar lavage (BAL).

Quantitative Burn Wound Cultures by Biopsy

Teplitz demonstrated that quantitative bacterial counts of burn wound cultures correlated with histologic specimens showing invasion or colonization.¹⁴² Burn wound infection (often referred to as "burn wound sepsis" in surgical literature) is suspected when proliferating microorganisms exceed 10^5 per gram of tissue and when invasion of subjacent unburned tissue has occurred (Fig. 76.2). The presence of microorganisms within the necrotic eschar cannot be considered evidence of burn wound infection. Furthermore although a bacterial count of 10^5 per gram of tissue is likely to indicate bacterial invasion, this is not invariably true. Only histologic sections can indicate the level of infection. Therefore burn wound cultures always should be accompanied by histologic sections from the same area.^{120,121}

At the time that surgery is performed, the potentially infected tissues should be excised with a punch biopsy (Fig. 76.3) and divided into equal aliquots.⁵⁸ One aliquot should be placed into saline and delivered to the microbiology section for quantitative assessment. These biopsy samples are weighed aseptically and homogenized in a sterile tube in 3 mL of sterile saline. Known dilutions of the homogenate then are

FIG. 76.2 Photomicrograph of a homogenized biopsy specimen stained with Gram stain. Gram-positive cocci are seen (cultures grew group A streptococcus at greater than 10^5 colony-forming units/gram tissue). (From Hunsicker L, Heggers JP, Patel JA. Infections in burn patients. In: Patrick CC, ed. *Clinical Management of Infections in Immunocompromised Infants and Children*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2001:338.)

FIG. 76.3 Use of a 6-mm punch for collecting a skin biopsy specimen for tissue histology and quantitative culture. (From Hunsicker L, Heggers JP, Patel JA. Infections in burn patients. In: Patrick CC, ed. *Clinical Management of Infections in Immunocompromised Infants and Children*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2001:339.)

plated using precalibrated loops (10 μ L) onto blood agar, colistin-neomycin agar, MacConkey agar, and Sabouraud agar for identification in initial dilutions of 0.1 mL with a 1-mL sterile pipette. After 24 hours, the number of colonies are counted and the quantitative wound culture is calculated according to the following formula:

$$\text{Colony-forming unit} \times \text{g of Tissue} \times \text{Number of colonies} \\ \times \text{Volume} \times \text{Dilution weight of biopsy in grams}$$

Despite the dependence on quantitative tissue cultures, reliability of this procedure has been questioned because of the high degree of variability in quantitative counts. Woolfrey and colleagues found that when biopsy samples were divided and cultured separately, only 38% of paired quantitative results agreed within the same \log_{10} unit, whereas 44% differed by 2 \log_{10} units or more.¹⁵⁶

Histologic Procedures

Standard histologic procedures, as well as cryostat examination, are necessary.¹²¹ The tissues should be examined for morphologic changes and for the presence of pathogens. Many bacterial and fungal pathogens can be identified by staining with Gram stain and Gomori methenamine silver stain (Fig. 76.4). More specialized stains may be necessary to identify other fastidious bacteria and fungi. Tzanck stain can be used to identify inclusion bodies suggestive of invasion of HSV or VZV. Viral-specific antibodies also can be used to detect these viruses by immunohistochemistry. The microbial status of the burn wound (i.e., colonization or invasion), as assessed by histologic examination of a biopsy specimen, can be graded on the basis of the density and depth of penetration of microorganisms (Box 76.1).¹²¹

Bronchoalveolar Lavage

BAL fluid needs to be collected by personnel experienced in the evaluation of patients with inhalation injury who are at risk for developing airway edema and obstruction. Ventilator-associated pneumonia can be diagnosed if 10^4 or more organisms per milliliter are cultured. In a study reported by Wahl and colleagues, BAL eliminated the unnecessary antibiotic treatment of 21% of patients.¹⁴⁸ In winter months, BAL fluids

Infections in burn patients. In: Patrick CC, ed. *Clinical Management of Infections in Immuno-compromised Infants and Children*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2001:338.)

BOX 76.1 Staging of Microbial Status of the Burn Wound by Biopsy Histology

Stage I: Colonization

- A. Superficial: Microorganisms present only on burn wound surface
- B. Penetrating: Variable depth of microbial penetration of eschar
- C. Proliferating: Variable level of microbial proliferation at nonviable-viable tissue interphase (subeschar space)

Stage II: Invasion

- A. Microinvasion: Microorganisms present in viable tissue immediately subjacent to subeschar space
- B. Deep invasion: Penetration of microorganisms to variable depth and expanse within viable subcutaneous tissue
- C. Microvascular involvement: Microorganisms within small blood vessels and lymphatics (thrombosis of vessels common)

Modified from Pruitt BA, Foley FD. The use of biopsies in burn patient care. *Surgery*. 1973;73:887–97.

also can be processed for prevalent respiratory viruses such as respiratory syncytial virus (RSV), influenza A and B viruses, and adenoviruses by rapid antigenic detection by immunoassays that are within the capability of most laboratories. Other respiratory viruses, as well as herpesviruses such as HSV and CMV in the respiratory tract, may be detected by viral culture or molecular diagnostics performed by a specialized virology laboratory or reference laboratory.

Local and Systemic Viral Infection

Viral culture or molecular testing using qualitative or quantitative PCR of the wound surface obtained by swab or by tissue obtained by biopsy will detect the presence of HSV or VZV. Disseminated viral infection with HSV, VZV, CMV, and other viruses may be evaluated by sending whole blood or plasma for specific viral DNA detection and quantification by PCR.

PREVENTION AND TREATMENT OF INFECTION

Care of the wound is the mainstay of burn therapy. The goal is to minimize infection and facilitate healing of the burn wound. Wound care addresses both partial- and full-thickness burn injuries until all wounds are closed.

Wound Dressing

The superficial epidermal layer provides a barrier to microorganisms while the deeper lipid epidermal layer provides protection against loss of water vapor. In full-thickness burns, the eschar may extend beyond the skin into the subcutaneous fat and muscle. Closure of the wound cannot occur until the eschar is removed. Bacterial proteases lead to eschar pseudoseparation and are slowed with antiseptic therapies. Then the eschar is allowed to fragment and slough, with resultant decreased size. This process is called *wound contraction*. This eschar can also be excised and skin grafted. Full-thickness skin grafts have the least contraction rates. Deep dermal wounds allowed to heal spontaneously lead to hypertrophic scarring. Compression garments are used to prevent and treat hypertrophic scarring.

When approaching burn wound care, a plan must first be decided. Outer burn dressings provide comfort, metabolic enhancement, and protection. First, superficial burns are exquisitely sensitive to air currents, as are deeper burns after some healing. Also, dressings provide splinting and drainage containment. Next, occlusive dressings help eliminate shivering, cold stress, and evaporative heat loss. In open, granulating wounds, loss of water vapor is maximal. Finally, the protective component deals with the control of topical organisms. Supplies consist of large 9 × 9 inch burn gauze, Kerlix wraps, Ace wraps, and topical antimicrobial agents. Gentle cleansing of the wound and daily debridement also are important. Buttock burn wounds should be examined carefully and frequently for the presence of deep stool staining, an ominous predictor of burn wound sepsis and death.¹²⁴ Such wounds should be emergently excised.

Topical Antimicrobial Agents

Topical antimicrobial agents are used extensively in burn patients. Most patients with stage I and stage II A and B wounds (see Box 76.1) can be treated with topical or subeschar antimicrobial agents alone.

Silver Sulfadiazine (Silvadene, SSD, Thermazene, Flamazine, Burnazine)

Silver sulfadiazine is a 1% water-soluble cream combining sulfadiazine with silver (Ag^+). The Ag^+ ion binds with the DNA of an organism and consequently releases the sulfonamide that interferes with the intermediary metabolic pathway of the microbe. It is most effective against *P. aeruginosa*, the gram-negative enteric bacteria, and *C. albicans*. *S. aureus* and some strains of *Klebsiella* spp. have been less effectively controlled.⁴³ Caution is advised with use of sulfadiazine products because cases of *P. aeruginosa* resistance to sulfadiazine have been reported.⁵⁷ When compared with collagenase ointment, topical silver sulfadiazine has been shown to be associated with lower rates of wound infection.¹¹⁷ Antimicrobial effectiveness has been observed to last for up to 24 hours. More frequent changes are required if a creamy exudate forms on the

wound. The benefits of this topical agent are its ease of use and its ability to reduce pain. It has some tissue-penetrating ability, but it is limited to the epidermis.

Silver sulfadiazine can be used separately or in combination with other antibacterial agents or enzymatic escharotomy compounds. It can be combined with nystatin, which enhances the antifungal activity of this agent. By itself, silver sulfadiazine has been shown to retard wound healing; however, in conjunction with nystatin or aloe vera, the wound-retardant effect is reversed. When topical silver sulfadiazine was compared with the more expensive collagenase ointment for treatment of partial thickness burns in children, there was no significant difference in clinical course, outcome, or need for skin grafting.¹¹⁷

Cerium Nitrate–Silver Sulfadiazine (Flammacerium)

The lanthanide salt cerium nitrate has been added to silver sulfadiazine since the 1970s and has been shown to have increased bacteriostatic effect in large burn wounds. The antimicrobial spectrum is similar to that of silver nitrate. Methemoglobinemia has been seen only rarely, and no associated electrolyte disturbances occur. Only minimal cerium absorption has been noted in patients with large burns treated for weeks. No complications were noted. Its use is somewhat limited because it is not commercially available in the United States. It is, however, available in several western European countries. Koller and Orsag studied the effects of cerium sulfadiazine in 20 burn patients and found it to be safe and effective in the treatment of deep, extensive burn wounds.⁸⁰

Silver Nitrate

Silver nitrate is available as a 0.5% solution that does not injure the regenerating epithelium in the wound and provides bacteriostatic effect against *S. aureus*, *E. coli*, and *P. aeruginosa*.⁴³ Silver nitrate is most effective when the wound is cleansed carefully of all emollients and other debris. Multilayered coarse mesh dressings should be placed over the wound and saturated with the silver nitrate solution. Like silver sulfadiazine, silver nitrate has limited penetration because the Ag⁺ ion is bound rapidly to the body's natural anions such as Cl⁻. Because it is hypotonic, it can cause osmolar dilution, resulting in hyponatremia and hypochloremia. Serum electrolyte levels should be monitored very carefully.

Notable detriments to the use of silver nitrate include its high expense and light sensitivity. Furthermore it also requires special handling because if it is allowed to dry or if it is covered with an impervious dressing hyperpyrexia could occur. *Klebsiella*, *Providencia*, and other Enterobacteriaceae are not as susceptible to it as are other bacteria. *E. cloacae* and other nitrate-positive bacteria can cause methemoglobinemia by converting nitrite to nitrate.

Mafenide Acetate (Sulfamylon)

Mafenide acetate is available both in a 10% water-soluble cream or a 5% solution and has more substantial bacteriologic data to support its efficacy than do any of the other topical antimicrobial agents.^{85,99} It has been shown to be effective against a broad range of microorganisms, especially against all strains of *P. aeruginosa* and *Clostridium* spp.¹²⁸ After a wound has been cleansed of debris, mafenide acetate is “battered” onto the wound. The treated burn surface is left exposed for maximal antimicrobial potency. The cream is applied a minimum of twice a day and can be reapplied as needed. The 5% solution is applied every 8 hours.

Additionally mafenide acetate has the ability to permeate burn eschar and thereby reduce the risk for bacterial colonization of a deep burn wound, and it is especially effective after the dead tissue is removed from the granulating bed. Unfortunately several detrimental aspects are associated with the use of mafenide acetate. Protracted use with the low environmental pH favors the growth of *C. albicans*. Mafenide acetate is converted to p-sulfamoyl benzoic acid by monamine oxidase, which is a carbonic anhydrase inhibitor; it subsequently causes metabolic acidosis in the patient. It also is painful when applied to superficial, partial-thickness burns with intact free nerve endings, and its requirement to remain uncovered for antimicrobial activity may be considered a disadvantage when a dressing is required.

Membrane Dressings

Acticoat and Aquacel are silver-coated dressings that have a broad antibacterial activity. Compared with silver nitrate or silver sulfadiazine use, Acticoat and Aquacel have been found easier to apply, were associated with less pain on removal, and have faster rates of reepithelialization.^{23,143} In one clinical study, Acticoat was found to have better antibacterial activity than silver sulfadiazine.⁷⁶ Acticoat is also better than hydrogel (Solosite) and paraffin-embedded woven cotton fabric (Jelonet) in protection against wound colonization/infection.¹⁴⁹ Mepitel is another gridlike, silicone-coated, nylon dressing used in treatment of partial-thickness burn wounds. Gotschall and associates found this product to decrease the pain experienced during dressing change, the time needed for the wound to heal, and the overall duration of the hospital stay as compared with silver sulfadiazine.⁴⁹ This study did not find any difference in the incidence of infections between Mepitel and silver sulfadiazine treatments.

Topical Antibiotics

Several topical antibiotics have been tried in the management of burn infections. The use of these agents is highly discouraged in a burn unit because of rapid emergence of resistance:

1. *Gentamicin sulfate*: Available as a 0.1% water-soluble cream, this antibiotic is chemically similar to the other aminoglycosides, such as kanamycin and neomycin. It has a broad spectrum of antimicrobial activity. It is used for its activity against *P. aeruginosa*; however, its topical use is highly limited because of the high level of gentamicin resistance in burn units.
2. *Bacitracin/polymyxin*: This antibiotic combination has little or no effect on localized infections of burn wounds.
3. *Nitrofurantoin*: This agent is used topically as adjunctive therapy in patients with second- and third-degree burns. With good eschar penetration, it can be used in the treatment of invasive burn wound infections with sensitive agents. The drug presents some advantages for the ambulatory patient. Tissue granulation begins sooner and crusts separate more rapidly.
4. *Mupirocin (Bactroban)*: Studies at Shriners Hospital for Children–Galveston have shown mupirocin to be superior to silver sulfadiazine in treating MSSA or MRSA infection.¹³⁸ Although mupirocin is weaker against gram-negative bacteria, it is also comparable to silver sulfadiazine and mafenide acetate against *P. aeruginosa*, *E. coli*, and *K. pneumoniae*. However, caution is advised for routine use of mupirocin in management of burn wound infection because it has been shown to lead to rapid development of resistance when it is used repeatedly.

Nystatin (Mycostatin, Nilstat)

Studies have shown that combining nystatin and silver sulfadiazine or nitrofurantoin results in effective prevention of local and systemic *Candida* infections, as well as burn wound sepsis.⁵⁹ However, in combination therapy with silver sulfadiazine and nystatin, mafenide acetate actually loses its antimicrobial activity. Therefore, use of nystatin with mafenide acetate is discouraged. Concentrated nystatin powder has also been studied for its effects on angioinvasive fungi (e.g., *Fusarium*, *Aspergillus*) refractory to systemic amphotericin B and serial excisions, including amputations.¹¹ A concentrated form of nystatin (6 million units/g) was used as dry aerosol every 6 hours with wet-to-dry dressings laid on top. Within 14 days, eradication of invasive fungal infections was noted in all four of the children studied. Also, all areas previously autografted underneath the nystatin powder healed well.

Sodium Hypochlorite (0.025% Heggers Solution)

Currently the most effective topical antibacterial agent for cleansing a wound is sodium hypochlorite (NaClO). It transcends the topical antimicrobial effects and tissue toxicity of such products as povidone-iodine, acetic acid, and hydrogen peroxide. The efficacy of NaClO has been determined to be at a concentration of 0.025%, which is bactericidal, is nontoxic to fibroblasts, and does not inhibit wound healing provided buffers are used.⁶⁰ It is a broad-spectrum antiseptic and is bactericidal for *P. aeruginosa*, *S. aureus* (MRSA and MSSA), enterococci, and other gram-negative and gram-positive organisms.¹²⁸

Povidone-Iodine (Betadine)

The active antimicrobial component in this compound is the iodine. It has a broad spectrum of antibacterial and antifungal activities. However, there are disadvantages that limit its use in a burn center. It is painful when applied and is inactivated by wound exudates. Renal dysfunction and acidosis have been noted in association with systemic absorption when applied to open wounds.

Chlorhexidine

Chlorhexidine when combined with 0.5% silver nitrate has efficacy similar to that of silver sulfadiazine.⁸⁹ Some variants of this product have broader antimicrobial activities, but pain experienced by patients on application has limited its use. Unlike the sulfonamides, plasma-mediated resistance has not occurred.

Citric Acid

In a study from India,¹⁰⁹ citric acid was formulated into a 3% gel and was compared with silver sulfadiazine. Citric acid gel application was better in wound healing. However, large-scale studies are lacking.

Subeschar Antibiotics

Moncrief has described the technique of subeschar antibiotic infusion.¹⁰² It is used for microbial invasion into unburned tissue when topical therapies have not been effective or in cases in which treatment has been delayed. The most common drugs used are tobramycin, gentamicin, and kanamycin. However, development of antimicrobial resistance is likely to be substantial, so subeschar infusion of antibiotics should be used infrequently. The antibiotic solution is administered via multiple needle infusions by subcutaneous lysis. The results of this technique are more rapid separation of eschar. The fluid infusion limit is 2000 mL (adult dose) and should be accounted for in a patient's fluid requirements. The infusion fluid should consist of 0.25 to 0.45 normal saline to avoid salt overload. Use of lactated Ringer solution should be avoided because some of the drugs are incompatible with calcium. Erythromycin has been studied but is too painful to use. Colistin, novobiocin, and cephaloridine have been used but found to be ineffective.

Systemic Antiinfective Agents

Drug pharmacokinetics are significantly altered in the burn patient and show significant interpatient and inpatient variation.¹⁵² Dolton and coworkers showed that vancomycin clearance is significantly higher in burn patients, but there is no significant difference in the volume of distribution.³² Doh and associates also showed that meropenem clearance and volume of distribution were higher.³¹ These studies suggest that higher dosing of vancomycin and meropenem may be needed in burn patients. Despite these studies, however, a review of the currently available literature shows that for many drugs there is a paucity of information to support current dosage recommendations, specifically in children of various age groups. In addition, many reports are based on small numbers of patients, and, even in larger studies, no standardization of the study population exists with regard to the important variables known to affect drug handling. For the subpopulation of burn patients who eliminate drugs extremely rapidly, a concern exists over the adequacy of antibiotic dosing. Researchers have suggested that antibiotic serum concentrations be measured, when available, in every patient to ascertain whether a significant problem exists with dosing.

Whereas stage I and stage II A and B wounds (see Box 76.1) can be treated with topical or subeschar antimicrobials alone, stage II C wounds require the immediate institution of systemic antiinfective agents. Systemic agents also are indicated for the treatment of various systemic infectious complications (see earlier discussion). Detailed information on selection of the appropriate systemic antimicrobial agents for specific bacterial, fungal, and viral pathogens is available elsewhere in this text. Nonetheless the following general principles can help guide the use of antimicrobial therapy:

1. Each antimicrobial agent must be selected for its specificity for the microbe present.
2. Such decisions should be made on appropriately collected culture and susceptibility data.
3. Colonizing flora should be distinguished from those responsible for inflammation and invasion.

4. The time, dosage, route of administration, and duration of treatment should be in accordance with what is required to make the organism nonpathogenic.
5. The need for broad-spectrum antibiotics should be balanced with the risk for promoting fungal infections.

Probiotics

Since burn injury results in exposure to MDR organisms in the hospital setting and the additional pressure of broad-spectrum antibiotics significantly alters the microbiome of the host, attempts have been made to reintroduce protective bacteria through the use of probiotics. No specific recommendations exist for the routine use of probiotics in the burn setting because there is concern for the potential for bacterial translocation and infection by the probiotic bacteria. Nonetheless some studies show encouraging results. Tahir and coworkers studied 64 Pakistani children with burns up to 50% TBSA; compared with controls, after treatment with an oral combination formulation of *Lactobacillus acidophilus*, *L. delbrueckii*, *Bifidobacterium*, and *Streptococcus thermophiles*, the loss of skin graft and mortality rates were modestly lower.¹⁴¹ In a study of a small number of children, Mayes and coworkers showed that use of *Lactobacillus rhamnosus* was associated with a modest trend toward reduced antifungal use, diarrhea episodes, requirement for excision or graft procedure, and wound healing period.⁹⁷ Additional studies of a larger number children are needed.

Treatment of Multidrug-Resistant, Gram-Negative Bacteria

This issue deserves specific mention because it most severely affects burn units. As noted in the earlier review of burn wound microbiology, in many centers, MDR and extensively drug resistant (XDR) bacteria, particularly *P. aeruginosa* strains and *Acinetobacter* spp., are identified frequently. For ESBL strains, the drug choice is a carbapenem. Newer agents effective against ESBL bacteria include combinations of a cephalosporin with β -lactamase inhibitors; examples include ceftolozane/tazobactam and ceftazidime/avibactam.

For carbapenemase-producing bacteria, colistin and polymyxin B often remain the only effective antimicrobial agents. Gerverman and coworkers have summarized their experience in 14 children treated with intravenous colistin: a favorable response was obtained in 79%, and the overall mortality rate was 14%.⁵⁰ Both colistin and polymyxin B are associated with significant elevation in serum creatinine value or with renal failure in 15% to 25% of recipients. Neurotoxicity in children is an infrequent occurrence. Intravenous and/or aerosol polymyxin B, doxycycline, and ampicillin/sulbactam (the active component is thought to be sulbactam) have been tried in XDR *Acinetobacter* infections as well.¹¹² Fosfomycin is also effective against carbapenemase-producing bacteria, but *Acinetobacter* spp is intrinsically resistant to it. Other studies have demonstrated in vitro susceptibility of XDR *Acinetobacter* to various synergistic combinations of antimicrobial agents, including carbapenems, colistin, rifampin, tigecycline, and ampicillin-sulbactam.^{47,62,158} A significant challenge in managing children with these antibiotics is that their dosage is often unknown because their pharmacokinetics have not been studied across different pediatric age groups, and most have no regulatory approval for pediatric use.

Treatment of Viral Infections

If HSV or VZV infection of the wound surface, lungs, or disseminated viral infection with viremia is present, then systemic antiviral treatment with acyclovir is indicated. Pneumonitis and systemic infection with significant viremia with CMV should be treated with ganciclovir. If viral resistance to first-line antiviral agents occurs, then foscarnet or cidofovir may be administered. Respiratory tract infection, including pneumonia associated with influenza A or B virus may be treated with oseltamivir, which can be orally administered if the patient is able to absorb enterally administered medications.

Antibiotic Prophylaxis

Prophylactic use of antibiotics remains a highly controversial topic. Penicillin prophylaxis is used commonly in many burn centers during outbreaks of group A streptococcal infections.^{52,125} Prophylactic antibiotics also are used before surgical manipulation or instrumentation because

the risk for developing bacteremia is as high as 50%. The choice of perioperative antibiotics depends on the knowledge of existing microorganisms, which are present not only on injured skin but also in the wound that is ready for surgery. Nonetheless carefully controlled studies are necessary to identify the value of prophylactic antibiotics.

In a placebo-controlled study of cefazolin use in children with burn injury, researchers found that in children with burns of less than 35% TBSA, cefazolin was not necessary, and in those with burns of 35% or more, it was not effective.¹²⁶ In a retrospective review study, antibiotic prophylaxis was not associated with any reduction in the rate of wound infection; instead the duration of hospitalization was found to be longer.³⁴ A recent meta-analysis of studies of prophylactic antibiotics found that most of the studies were weak.⁵ The most important finding was that staphylococcal infection rates declined with prophylaxis but resistance to prophylactic antibiotics increased. In a study by Mulgrew and coworkers, prophylactic antibiotic was found to have no effect on the occurrence of TSS in children.¹⁰⁶ Tagami and coworkers used a nationwide database of hospitalized burned children in Japan; use of antibiotic prophylaxis was associated with improved 28-day in-hospital mortality in mechanically ventilated patients but not in those who were not mechanically ventilated.¹⁴⁰ In another study, routine intranasal mupirocin use at admission was not associated with reduction of burn wound colonization.⁶⁷

Wound Excision and Grafting

Studies have shown that early excision of wounds leads to significantly decreased rates of bacterial colonization and wound infection.¹⁰ In a meta-analysis of six trials, it was found that early excision of burns is beneficial in reducing mortality (in patients without inhalational injury) and length of hospital stay. The only drawback is the greater volume of blood loss.¹¹⁴

Gut Support and Decontamination

The gut microflora have been implicated in the development of multiorgan failure when the gut barrier fails. Hence one theory is that early enteral feeding of the gut, which promotes function of the gut barrier, is important for preventing multiorgan failure. A decontaminated gut with nonabsorbable, broad-spectrum antibiotics might diminish the impact of failure of the gastrointestinal barrier. Although the suggestion has been made that the rate of pneumonia may be decreased by such maneuvers, no apparent impact on mortality rates has been noted.⁹⁴ Overall, convincing human data on the beneficial effect of enteral feeding and decontamination of the gut on sepsis and multiorgan failure are lacking.

Immunomodulators

In view of the intricate relationship between altered immune defenses in burn patients and increased susceptibility to infections, various types of immunotherapies have been tried. In an Italian study, treatment with intravenous pooled immunoglobulin (IVIG) was found to have a beneficial effect on septic phenomena and recovery.¹⁰⁰ However, in two U.S. studies, no change in rates of infection or mortality was shown. Overall the beneficial role of IVIG as prophylaxis or treatment remains unproved.^{108,150} In a German study, prophylaxis with intravenous anti-*Pseudomonas* immunoglobulin did not appear to be beneficial to burn patients in general; however, it was shown to be effective in burn patients with inhalation injury.¹³⁹ In a South African study, prophylaxis with high-titer anti-lipopolysaccharide immunoglobulin G reduced the incidence of burn wound infection but did not affect mortality.⁷⁰ Benefits of plasmapheresis or fresh frozen plasma infusion have not been proved.

INFECTION CONTROL

Hospital-acquired infections in burn patients are common occurrences. In pediatric burn patients, wound infections, ventilator-related pulmonary infections, central-line bacteremias, and catheter-associated urinary tract infections are the most common nosocomial infections.^{129,151} The rates of infections may be lower than those seen in adults, but urinary tract infections occur more frequently in children.¹²⁹ In a German study of children with burns, the overall infection rate was 59.7 nosocomial

infections per 1000 inpatient days, and the device-associated infection rates per 1000 device days were 55.2 for pneumonia, 8.9 for primary bloodstream infections, and 41.7 for urinary tract infections.⁴⁵ The incident density of burn wound infections was 18.5 per 1000 inpatient days, which was associated with the percentage of TBSA of the burn wound. On the other hand, the rate of device-associated infections was not associated with the percentage of TBSA.

Surveillance of infection in a burn patient is performed to implement prompt treatment on the basis of surveillance cultures and antimicrobial sensitivities at the earliest sign of invasion. Such surveillance requires cultures of sputum, urine, and wounds about three times weekly; however, the need for such cultures and the frequency of monitoring remain controversial. Additional infection control measures involve surveillance of spread of pathogens among burn patients in a burn unit. In dealing with the burn wound, strict infectious disease precautions must be maintained to prevent contamination and worsening infection in these already immunocompromised patients.

In the past, poor hand-washing and shared hydrotherapy tubs were the source of many infections, some of which were life threatening. Strict enforcement of hand-washing and use of gowns, gloves, and masks have led to decreased rates of patient contamination. Also, disposable hydrotherapy tub liners are used to eliminate the risk for patient-to-patient transmission of infections.¹⁴⁴ In addition, isolation of burn patients in a single room compared with placing them in an open ward has dramatically affected infection rates. McManus and associates studied this measure in 2519 patients and found significantly lower incidence and mortality rates associated with gram-negative bacteremia in the isolated patients.⁹⁸ Also those patients in an open ward who had bacterial isolates showed significantly more antimicrobial resistance compared with patients in isolation.

Additional infection control measures include the daily use of germicidal solutions to clean all hardware, such as intravenous poles and pumps, monitoring equipment, bedside tables, and beds in patients' rooms. On discharge of the patient, everything in the room, including floors, walls, ceilings, and mattresses, must be cleaned with germicidal solutions. Air filters should be monitored repeatedly for fungal and bacterial growth.

Lai and colleagues studied the effects of strict isolation of patients with vancomycin-resistant enterococci, the use of vancomycin, and the cost-to-benefit analysis of barrier precautions.⁸⁶ The study showed that pharyngeal swabs were poor for surveillance but that rectal swabs were more useful. Also guidelines for use of vancomycin were adhered to by 85% of the staff. The overall cost for these implementations, including the barrier supplies and cleaning protocols, was \$11,000. Nonetheless vancomycin-resistant enterococci were not eradicated. On the other hand, van Rijn and colleagues¹⁴⁶ have shown that isolation in a quarantine unit was highly effective in preventing outbreaks of MDR bacteria.

Kawasaki Disease

Stanford T. Shulman • Anne H. Rowley

Kawasaki disease (KD) is a multisystem acute febrile vasculitic syndrome of presumably infectious origin that affects predominantly infants and young children. The diagnosis is based on characteristic clinical features (Box 77.1). Serious complications include coronary arteritis, coronary artery aneurysms and stenoses, coronary thrombosis leading to myocardial infarction, and, very rarely, rupture of a coronary aneurysm. KD has become the leading cause of acquired heart disease in children in most developed countries, including the United States and Japan.^{307,308} It has been reported in children of all racial groups and from all continents. Although the etiology of KD remains unknown and a specific diagnostic test is lacking, establishing a timely diagnosis is very important because administration of intravenous immunoglobulin (IVIG) and aspirin before the 10th day of illness generally has a dramatic effect on the clinical manifestations and markedly reduces the likelihood of development of coronary abnormalities (see the later sections on treatment).^{87,196–199,267,311}

Synonyms for KD include *Kawasaki syndrome* and *mucocutaneous lymph node syndrome* (MCLS, MLNS, or MCLNS). The disease also has been referred to as *lymphomucocutaneous syndrome*. An earlier term used in autopsy reports was *infantile periarteritis nodosa* (IPAN), which is pathologically indistinguishable from fatal KD. The International Classification of Diseases (ICD-9) designates the condition as both KD and mucocutaneous lymph node syndrome (acute) (febrile) (infantile) under rubric 446.1 and ICD-10 under M30.3. Before 1983, the National Library of Medicine listed KD publications under various subject headings, particularly “Lymphatic Diseases.” Since 1984, publications have been listed under “Mucocutaneous Lymph Node Syndrome,” a name that has been replaced by KD.

HISTORY

The illness now bearing his name was first recognized as a clinical entity in 1961 by Dr. Tomisaku Kawasaki, who subsequently became chairman of the Department of Pediatrics at Tokyo's Japan Red Cross Medical Center. Between 1961 and 1967, Kawasaki identified 50 infants and young children who manifested a distinctive constellation of signs that included prolonged high fever, unilateral cervical lymphadenopathy, bilateral conjunctival injection, a polymorphous erythematous rash, changes of the mucosa of the lips and oral cavity, and edema and erythema of the extremities, with subsequent desquamation of the finger and toes. Although the syndrome was distinctive, its signs were nonspecific. Laboratory tests ruled out other disorders. A series of the first seven cases was presented by Kawasaki at the 61st Chiba General Meeting of the Japan Pediatric Society in 1962.¹³³ Convinced that he was observing a distinct clinical syndrome, Kawasaki published a report of his experience with 50 cases of “febrile oculo-oro-cutaneo-acrodesquamatus syndrome with or without acute nonsuppurative cervical lymphadenitis” in 1967.^{134,135,137} Other Japanese physicians quickly recognized the syndrome after Kawasaki's report, although considerable discussion ensued about whether it was a distinct entity or an illness related to Stevens-Johnson syndrome.¹³⁶

Cardiac involvement in this illness was suspected first in 1968, when Yamamoto and Kimura reported an infant with KD who had transient tachycardia with a gallop rhythm, cardiomegaly, and minor electrocardiographic (ECG) abnormalities.³³⁹ In 1970, Kawasaki obtained funding to establish the Research Committee of Mucocutaneous Lymph Node Syndrome, sponsored by the Japanese Ministry of Health and Welfare, which was organized with Dr. Fumio Kosaki as chair.¹³⁷ In the first

national survey of this committee, four autopsied and six nonautopsied cases of children who had died of coronary artery complications after apparent KD were identified.¹⁴⁷ These children were predominantly younger than 2 years of age and had died suddenly within 30 days of onset of disease, with evidence of coronary aneurysms and acute thrombosis. The first biennial Japanese national epidemiologic survey was conducted by this committee in 1970 under the leadership of Dr. I. Shigematsu and was published in 1972.²⁶⁴ By this time, it had become well established that some patients who recovered apparently uneventfully from this acute illness were at risk for sudden cardiac death, with findings of acute myocardial infarction secondary to thrombosis within coronary arteries damaged by a severe vasculitic process.¹⁴⁷

In 1971, physicians at the University of Hawaii who were unaware of the Japanese experience began to recognize patients with an unusual Reiter syndrome–like illness. When information about KD was published in the English-language literature,¹³⁷ the illness in Hawaii was recognized clearly as KD. Information exchanged between Japanese and U.S. investigators led to the 1974 publication of English-language articles by both groups^{137,172,173} and triggered worldwide recognition of cases. In the early 1970s, death from myocardial infarction was reported to occur in approximately 2% of cases of KD; more recent data reflect much lower mortality rates of less than 0.02%.^{105,188,327,345} Four deaths were recorded in Japan among 26,691 patients in 2011 to 2012 (0.015%). Four deaths occurred among 23,349 KD patients in Taiwan from 2000 to 2010 (0.017%).¹⁶³ With the availability of echocardiography in the late 1970s, researchers determined that 20% to 25% of patients developed evidence of coronary artery abnormalities.¹²³

In the decades before Kawasaki recognized the clinical features of the illness, many individual reports of fatal coronary arteritis in children (usually labeled IPAN) were published in the non-Japanese pediatric and pathology literature.^{48,72,182,218,232,237} Clinical details of these cases generally are highly suggestive of KD, and the pathologic features of IPAN are indistinguishable from those of KD, as demonstrated conclusively by Landing and Larson in 1977.¹⁵² Almost 100 years before Kawasaki's description was published, Samuel Gee of St. Bartholomew's Hospital in London in 1871 reported the case of a 7-year-old boy who at death (“following scarlatinal dropsy”) had three coronary aneurysms, each filled with a fresh clot; histologic examination of that patient's cardiac tissue is compatible with inactive KD with extensive coronary luminal myofibroblastic proliferation.^{90,274,271} Shibuya and colleagues retrospectively identified cases of illnesses compatible with KD that occurred in Japan up to two decades before Kawasaki's description was published.²⁶³ Likely, patients with KD in previous decades were misdiagnosed as having measles, scarlet fever, rubella, or other once common conditions, and reductions in the numbers of cases of those illnesses helped to facilitate recognition of KD.¹³⁶

Kawasaki's clinical description of the syndrome has remained the foundation of diagnosis and the basis of the clinical and epidemiologic case definitions in use today (see Box 77.1). In 2017, the American Heart Association Committee on Rheumatic Fever, Bacterial Endocarditis, and Kawasaki Disease published updated guidelines for the management of patients with incomplete (or atypical) KD (see later discussion).^{171a,199,}

EPIDEMIOLOGY

Sources of Epidemiologic Data

In the absence of a confirmatory diagnostic test, the epidemiologic case definitions of KD are relatively strict and exclude from surveillance

BOX 77.1 Diagnostic Criteria for Classic or Typical Kawasaki Disease

Fever for at least 5 days^a plus four of the following features:

- Bilateral conjunctival injection
- Polymorphous exanthem
- Changes in the lips and oral cavity (erythema, cracking of lips; oropharyngeal erythema; strawberry tongue)
- Peripheral extremity changes (erythema and swelling of hands and feet; later periungual desquamation, Beau lines)
- Cervical lymphadenopathy (≥ 1.5 cm in diameter)

Exclusion of other diseases with similar features

The finding of fever plus three criteria in the presence of coronary abnormalities qualifies.

^aIn the presence of classic features, experienced clinicians may be able to establish the diagnosis before the fifth day of illness.

data other exanthematous conditions that could dilute “true” cases and thus could obscure secular trends. However, the original epidemiologic case definitions were not intended for clinical application, a very important point since effective treatment became available. Thus, less strict application of clinical case criteria is appropriate for management of patients. Clinicians must be aware that children often present with clinical illnesses that do not completely fulfill the diagnostic criteria for KD but who are nonetheless at risk for developing coronary artery sequelae and therefore warrant therapy. These patients generally are considered to have *incomplete* or *atypical* KD.^{22,86,199,251} Incomplete presentations of KD are particularly common occurrences in young infants in whom clinical signs often are subtle or fleeting but who are at the highest risk for development of coronary artery abnormalities.^{35,242} In the United States, the Centers for Disease Control and Prevention (CDC) case definition usually is used for epidemiologic purposes and the American Heart Association published an algorithm to aid in the diagnosis of incomplete (atypical) KD.^{171a,199} The current Japanese diagnostic guidelines were revised in 2014 and also reflect the importance of incomplete cases.¹¹⁷

Incidence Rates

The incidence of KD varies throughout the world and reflects primarily the racial composition of various countries. Rates in Japan have climbed steadily, with an annual rate of 243.1 per 100,000 children younger than 5 years of age in 2011 and 264.8 in 2012 (22nd national survey).¹⁶⁶ The highest reported rate in Korea was 134 per 100,000 children younger than 5 years old in 2009–11.¹⁴⁰ Taiwan has the third highest reported rate, 82.8 per 100,000 children less than 5 years old.¹⁶³ In countries with predominantly non-Asian populations, the rate is 15 to 20 per 100,000 children younger than 5 years.¹⁰⁷

Gender

In virtually all population-based studies in many countries, the ratio of male to female patients with KD approximates 1.5:1.^{166,327,347} In addition, serious and fatal complications also are significantly more common findings among male patients with KD compared with female patients.^{190,346} Examination of fatal Japanese cases indicated almost three times as many Kawasaki-related fatalities among males compared with females, with a higher ratio in infancy.^{190,327} The basis for the preponderance of KD in males and for the even greater predominance of serious coronary artery disease in males with KD remains unclear. Of interest is that a male predominance is observed in many infectious diseases.

Race or Ethnic Background

The first cases of KD were recognized in Japanese children and in Hawaiian children of predominantly Japanese ethnicity, and subsequent data consistently support higher rates in those of Asian background. Annual incidence rates in Japan have climbed steadily to 264.8 cases per 100,000 children younger than 5 years of age in 2012,¹⁶⁶ from 102.6 in 1995 and 184.6 in 2005 to 2006,¹⁸⁷ and they are the highest in the world, approached only by rates for Japanese-American children in

Hawaii (210.5 per 100,000 of children younger than 5 years).¹⁰⁸ More than 13,917 cases of KD were reported in Japan in 2012, with local clusters rather than nationwide epidemics, as were seen in 1979, 1982, and 1985–86.¹⁶⁶ In epidemic years in Japan, the annual age-specific incidence rates reached or exceeded 200 per 100,000 children younger than 5 years.³⁴¹ Incidence rates in white children in many communities are much lower, most often approximating 10 to 20 per 100,000 children younger than 5 years.^{55,107,269} Surveys in countries with almost exclusively white populations often yield rates of 5 to 10 cases per 100,000 children younger than 5 years.^{23,26,40,103,224,278} In Washington state, ethnic group-specific incidence rates per 100,000 children younger than 5 years were estimated to be 33.3 for Asian Americans, 23.4 for blacks, and 12.7 for whites.⁵⁵ In Hawaii, with its complex racial-ethnic makeup, the overall annual incidence is about 45 per 100,000 children younger than 5 years.¹⁰⁸ The yearly incidence for Japanese children in Hawaii approaches 200 cases per 100,000 children, and for whites it is 35 per 100,000, with intermediate rates for those of native Hawaiian and Chinese, Filipino, and other Asian ancestry.¹⁰⁷ Prospective Kawasaki disease surveillance in Germany in 2011–12 corrected for underreporting yielded an incidence of 7.2 per 100,000 children younger than 5 years.¹¹⁵ Extrapolation of data from surveys of U.S. hospitals with large children's services led to estimates of approximately 2500 cases per year in the United States from 1984 to 1993,^{307,308} with more recent estimates as high as 5000 cases annually.²⁹ A study of KD in the United States identified approximately 4200 hospitalizations in the year 2000, with highest rates among Asian and Pacific Islanders, lowest rates in whites, and intermediate rates in blacks and Hispanics.¹⁰⁷

Age

KD occurs almost exclusively in children. In the United States and Japan, adult cases are quite rare, although some reports of adults diagnosed by accepted diagnostic criteria have been published.¹⁵⁷ Many of these adult patients have been infected with human immunodeficiency virus (HIV).^{10,36,39,71,95,119,175,226,231,261} Most of the early reported adult cases, however, probably actually represented toxic shock syndrome or drug hypersensitivity reactions. Perhaps the best-documented adult case (confirmed by Dr. Kawasaki) was that of a 31-year-old Japanese man who later developed bilateral coronary artery aneurysms.²⁸⁸ Because the signs and symptoms are nonspecific, adults suspected to have KD should be evaluated carefully for infectious, toxic, and other possible causes of illness.

The distribution of KD by age in childhood is highly characteristic. The disease occurs most frequently in young children: 50% are younger than 2 years, 80% are younger than 5 years, and cases seldom occur in those older than 12 years.^{107,282,345} In 2009–10, 0.7% of Japanese patients with KD were 10 years old or older.³²⁷ Infants in the first 3 to 5 months of life have a relatively low incidence of KD, but the incidence rises rapidly from that point.³²⁷ In the United States, the peak age is about 10 months, whereas more recent data from Japan identified 25% as younger than 1 year, 88% as younger than 5 years, and the peak age incidence as 9 to 11 months of age.¹⁶⁶ In Hawaii, 29% of cases are in infants younger than 1 year, and 85% of patients are younger than 5 years.¹⁰⁷ The age-incidence curve may be helpful in elucidating risk factors for developing KD. Such a pattern is compatible with highly transmissible infectious agents, particularly respiratory agents, and suggests possible transplacental immunity. The features of 28 patients with KD who were aged 8 years and older at the time of diagnosis at Children's Memorial Hospital in Chicago have been reported.²⁸² Delays in establishing the diagnosis and in providing treatment were common occurrences and were at least partially related to the prominence of arthritic and gastrointestinal symptoms in this population. We recently cared for a 30-year-old man with classic KD.

Earlier Japanese mortality data suggested that fatality rates are approximately three times higher in children younger than 1 year at the time of onset of disease, compared with older children, and that fatalities occur predominantly in the first several months after onset of KD.³⁴⁴ Male patients account for a disproportionate number of deaths in infants and older children.^{105,186,327,344} Long-term mortality rates in a large Japanese KD cohort study were increased over background rates, particularly during and shortly after the acute stage of illness.^{188,190}

A Taiwanese series of 25 infants who developed KD at 3 months or younger included 19 males and 6 females. Only 6 infants met KD diagnostic criteria, with the other 19 classified as incomplete. Coronary artery involvement was noted in 80%, although only one infant had persistent abnormalities at 1-year follow-up.⁴⁵

Recurrent Kawasaki Disease

A recurrence of KD is defined generally as a new episode of illness meeting clinical criteria for KD that begins at least 3 months after the initial episode and after inflammatory markers such as the erythrocyte sedimentation rate (ESR) or serum C-reactive protein (CRP) level have normalized. The frequency of recurrences after first cases of KD in Japan was estimated to be approximately 1.9% during a 3-year follow-up period, with approximately 0.07% of patients experiencing a third episode.¹⁸⁷ This corresponds to a rate of 5.21 per 1000 person-years for one or more recurrences.¹⁸⁷ With longer follow-up, recurrence rates in Japan may approach 3%.³⁴⁶ Data from the United States suggest a recurrence rate of 1% to 2%.¹⁷ Recurrences occur most frequently within the first 2 years after the initial episode, especially in male patients and in children who have their initial episode before reaching their second birthday.¹⁸⁷ The frequency of recurrences in Chicago appears to be approximately 1%, occurring more often in Asian children, and recurrences were documented in about 2% of Hawaiian cases from 1996 to 2000,¹⁰⁸ a finding likely reflecting a racial difference. In the CDC's passive KD surveillance data, 97 of 5557 (1.7%) patients from 1984 to 2008 had recurrent KD, including 3.5% among Asian/Pacific Islander patients.¹⁶⁵ The true recurrence rate will be determined only when a specific diagnostic test becomes available for KD and thus minimizes recognition bias.

Family Cases

Simultaneous or sequential cases of KD in siblings, twins, or other family contacts also have been reported, particularly during outbreaks in Japan.^{81,111,169,347} Japanese epidemiologists have documented secondary sibling cases in approximately 1% of cases, a rate that is approximately 10 times greater than that in the general child population.⁸¹ However, such figures are difficult to interpret because they may be influenced by recognition and reporting biases. In the 2011–12 Japanese survey data, 1.5% of KD cases had one or more infected siblings, and 0.89% had at least one parent with history of KD.¹⁶⁶ Sibling cases are reported to occur more frequently in twins than in nontwins. Only three sibling pairs were recognized in more than 2100 Chicago patients, and none was reported in 400 children in Los Angeles.¹⁶⁸ A report from two US medical centers noted 18 families with multiple affected KD patients, including nine families with two affected siblings and nine with KD in two generations or in multiple affected members.⁵⁹

Epidemics and Outbreaks

Japanese investigators noted large nationwide outbreaks of KD in 1979, 1982, and 1985 to 1986, with wavelike spread occurring from one prefecture to the next, suggesting an infectious origin.^{189,340,342} The 1982 Japanese epidemic started simultaneously in four areas and spread outward from each region, similar to the way that epidemic influenza spreads in Europe and America.^{189,340} In the 1985–86 Japanese epidemic, investigators identified epidemic “waves” that spread outward from an initial focus in the Tokyo metropolitan area and extended simultaneously northward and southward to involve most of the country within approximately 4 months.^{189,340,342} A similar but less distinctive pattern of interprefectural progression in waves was noted in the 1982 Japanese epidemic. Within the northern Tohoku District, for example, KD spread from prefecture to prefecture over a period of approximately 7 months.³⁴⁰ Korean epidemics were detected 7 and 15 months after the Japanese epidemics of 1979 and 1985–86, respectively.^{156,340} More localized outbreaks also have been observed. In the United States and elsewhere, community-wide outbreaks were documented beginning in 1977.^{18,56,317} Investigation of outbreaks provides opportunities to study potential risk and etiologic factors. Clustering of cases within families, schools, or neighborhoods is quite unusual, even during large-scale epidemics. Japanese investigators have associated epidemics with a significantly increased likelihood of second cases occurring in families, fatalities,

and recurrent cases, but the implications of these findings are uncertain. It is striking that, since 1986, no further nationwide Japanese outbreaks have been identified, suggesting that the epidemiology of KD may have changed.^{260,348} However, it is important to recognize that the current endemic rate of KD in Japan exceeds that of the largest previous endemic.

Geography

KD has been diagnosed throughout the United States and Japan and in virtually all developed and many developing countries on all continents, including temperate and tropical zones.^{26,40,73,164,227,257,258,316} No striking rural–urban differences have been noted. Elevation, longitude, and latitude have not been implicated. Travel histories of patients are unremarkable, although an anecdotal report of a 7-month-old infant in Australia documented KD onset 17 days after leaving Japan during that country's 1982 epidemic,²⁷⁸ and we diagnosed KD in infant in Chicago about 2 weeks after moving from Japan.

Seasonality

In Japan, KD occurs year round but is most prevalent in the winter, with peaks usually occurring in December or January, with a lower peak in June, and the lowest number of cases in October.^{30,328,343,346} In Korea, peaks were observed in summer and winter²²²; in Taiwan, peaks occur in summer, with a nadir from November to January¹¹⁰; in Beijing and Shanghai, peaks occur in spring and summer⁶⁴; and in spring in Sichuan and Hong Kong.^{159,200} In the United States and other temperate areas, the number of cases peak in the winter and early spring and is lowest in late summer; nonetheless, cases occur throughout the year.^{17,19,42,107,168,233} No clear seasonality has been seen in Hawaii.¹⁰⁸ Winter predominance has been observed in at least some Southern Hemisphere countries.³² That sporadic cases are recognized year round is somewhat different from the pattern usually observed with highly transmissible respiratory viral diseases, incidences of which peak sharply in the winter and spring (e.g., measles, rubella, influenza), and virtually disappear in summer.

Communicability

Although little direct evidence exists that KD is transmissible from person to person, considerable circumstantial evidence supports an infectious origin. Secondary or co-primary cases in families occur but are not common. Several outbreak investigations found a higher rate of antecedent respiratory tract illness in patients with KD compared with matched controls.^{18,300} This finding is of particular interest in view of the finding that immunoglobulin A (IgA) plasma cells infiltrate the proximal respiratory tract and that viral-like inclusion bodies are observed in bronchial epithelial cells in fatal cases of KD, and it strongly supports a respiratory mode of spread of an inciting agent (see later discussion).^{246,255} Japanese family data suggest that sibling cases cluster either on the same day as the index case or 7 days later.⁸¹ Because these results are based on questionnaire data, however, the possibility of ascertainment bias is great; thus determining the degree to which Japanese familial cases represent co-primary or secondary cases is difficult.

Other Risk Factors

In addition to demographic risk factors for KD, specific exposures that could be related to an etiologic agent have been linked to the disorder by older epidemiologic investigations. History of more frequent recent antecedent respiratory illnesses in cases compared with controls was documented in the early 1980s.¹⁸ Because many viral agents are prevalent in the winter and spring when KD is most prevalent, some “background” isolation of various viruses from patients and from matched controls is expected.

Other past reported KD associations include exposure to recent carpet cleaning or shampooing, exposure to house dust mites, and residence near bodies of water; very few recent reports support these associations. The association of KD with exposure to recently cleaned or shampooed carpets was observed in some reports^{21,75,96,109,120,209,223,233,234} but not in others.^{52,160,179,233,240,241,309} The significance of a possible association with shampoo is unclear because it is absent entirely in many well-studied outbreaks and because carpets are relatively uncommon in Japan.^{52,179}

In a small number of outbreaks, investigators from the CDC found that patients with KD lived closer to bodies of water compared with control patients.^{234,235} However, other studies, including one in Washington state, did not find living in proximity to water to be a risk factor.⁵⁵

ETIOLOGY

The origin of KD remains unknown. However, clinical and epidemiologic features strongly suggest that the disease has an infectious cause. A self-limited, usually nonrecurring illness manifested by fever, rash, enanthem, conjunctival injection, swollen and red hands and feet, and cervical adenitis fits well with an infectious cause. The epidemiologic features noted earlier, including the striking age distribution, winter-spring seasonality in most areas, occurrence of community outbreaks with wavelike geographic spread, and apparent epidemic cycles, resemble those of a transmissible disease of childhood. The laboratory features, including leukocytosis with a “left shift,” elevated acute-phase reactants, mildly elevated liver transaminases, and pyuria also suggest infection. The medium-size muscular arteritis of KD may result from infection of arterial walls by the causative agent(s) with a subsequent immune response or an immune attack on presently unknown host molecules as a consequence of infection with the agent(s).

A very attractive hypothesis is that KD is caused by a ubiquitous infectious agent that produces clinically apparent disease only in selected, genetically predisposed individuals, with particular predilection for Asians. Its rarity in the first few months of life and in older children and adults suggests an agent to which virtually all adults are immune and from which very young infants are protected to some degree by passive maternal antibody. Consistent with this hypothesis is the paucity of evidence of person-to-person spread of KD, because most infections are likely asymptomatic, and only very few of those infected likely develop clinical features of KD. This would be analogous to acute poliomyelitis, the relatively uncommon complication of poliovirus infection that occurs in only approximately 1 in 200 of those infected. However, efforts to identify an infectious agent of KD using conventional bacterial and viral culture and serologic methods, as well as inoculation of primates, mice, and guinea pigs, have failed to yield an infectious cause, and a long list of known infectious agents proposed as the cause has been disproved.^{18,56,244} This includes *Leptospira* spp., retrovirus, TSST-1-producing *Staphylococcus aureus*, and coronavirus NL-63.^{62,244} An oligoclonal, antigen-driven immune response has been well-documented^{44,244,245,247}; whether a superantigen response also occurs in some children with KD is unclear³⁴⁹ and will likely require identification of the causative agent to be determined.

The immune transcriptional profile of coronary arteritis in KD has features of an antiviral immune response such as activated cytotoxic T lymphocyte and type I interferon-induced gene upregulation.²⁵⁶ Ultrastructural, immunofluorescence, and RNA evidence support the hypothesis of a presently unidentified “new” virus as the cause that enters through the respiratory tract and is carried by macrophages to the coronary arteries.^{244,245,248,250} Another hypothesis is that the agent of KD, possibly a fungal toxin, may be carried via the wind as an aerosol.^{238,239}

While some investigators suggest that KD can be triggered by any of a large number of diverse infectious agents in a genetically predisposed host,²⁸⁹ recurrence of KD is quite uncommon, and KD children appear to experience subsequent infections without developing KD again. This theory also fails to explain epidemics and the wavelike geographic spread of illness during outbreaks.

Identification of the etiologic agent(s) of KD is an extremely important research goal because diagnostic test development, development of improved and specific therapies, and prevention are critical to improved patient care and outcomes but will likely only be achieved after the etiology is determined.

Genetic Susceptibility

The higher rates of KD in those of Japanese and, to a lesser degree, Korean and Taiwanese backgrounds indicate a genetic basis rather than environmental factors, as supported by increased rates among third- and fourth-generation immigrants from Japan to Hawaii.¹⁰⁸ The increased incidence of KD among siblings and parents of patients also supports

a genetic predisposition.^{329,344} The genetic basis is complex, and no single human leukocyte antigen (HLA) or MHC class II gene is common to most patients with KD. Immunoglobulin allotypic markers were studied as possible genetic markers for KD, and differences between patients and race-matched controls were found in Japanese and whites, supporting a complex genetic basis for susceptibility to KD.²⁷⁰ Transmission disequilibrium studies involving children with KD and their parents demonstrated evidence of several functional single nucleotide polymorphisms in the calcineurin-NFAT pathway, the transforming growth factor- β (TGF- β) signaling pathway, and genes encoding Fc γ receptors. These studies show that single nucleotide polymorphisms (SNPs) within the inositol triphosphate kinase-3 (*ITPKC*) gene on chromosome 19 and in *CASP3* on chromosome 4 confer increased risk in Japanese, Taiwanese, and white children.^{34,149,213,214}

Genome-wide association studies (GWAS) to define KD susceptibility risk loci have accelerated identification of additional loci on chromosome 8 and other chromosomes.^{27,215,335} Davila and colleagues, also in a GWAS, identified a polymorphism in *FCGR2A* on chromosome 1 related to immune activation as a KD risk marker.⁵⁴ Other analyses have identified SNPs in *ITPKC* and *CASP3* that are associated with increased risk of IVIG unresponsive and coronary aneurysms.²¹⁶ Several additional loci have been identified in the Taiwanese population.³³⁵ The picture is emerging that there are more than 6 to 10 genetic susceptibility markers for KD, each of which is associated with some increased risk for KD compared with controls. Onouchi et al. recently reported an SNP in the *ORA1* gene in the Ca²⁺/NFAT pathway that is associated with KD in Japanese and that is present with 20 times higher frequency in Japanese compared to European populations.²¹² This is an area of intense research activity.

PATHOLOGY AND PATHOGENESIS

Relationship With Infantile Periarthritis Nodosa

When the first Japanese survey of KD in 1970 yielded reports of 10 deaths, the pathologic diagnosis was thought to be IPAN.^{116,138,147} Japanese and Western investigators quickly recognized the pathologic similarities between fatal KD and IPAN, long known to have an unusual predilection for the coronary arteries.^{1,15,16,302–305} In the most definitive study, Landing and Larson^{152,155} showed clearly that IPAN and fatal KD were indistinguishable pathologically. Published case reports of autopsies of children with IPAN frequently contain clinical histories that include many or all features of acute KD and the development of severe vasculitis affecting primarily the coronary arteries.²³⁷ The failure of some reported patients with IPAN to meet KD case criteria applied retrospectively is likely related to documentation bias and to the young age of many of the patients. Young infants with KD are less likely to have a classic presentation than are older children (see later discussion). When pathologic and clinical criteria are combined, the two diseases appear indistinguishable. Adult-type periarthritis nodosa was described first in 1866 by Kussmaul and Maier,¹⁵¹ and it differs from IPAN primarily by the presence of hypertension and involvement of small and medium muscular arteries, especially in the lung, kidney, and intestines.^{84,152,304,305} An early recorded case of possible IPAN dates from 1899.¹⁴⁸ In 1959, Munro-Faure¹⁸² very clearly delineated a syndrome of infantile necrotizing arteritis with coronary artery involvement, fever, rash, conjunctival and pharyngeal infection, and cervical adenitis, distinct from classic periarthritis nodosa. Roberts and Fetterman²³⁷ and others expanded on these observations to define a distinct clinicopathologic syndrome of IPAN shortly before Kawasaki recognized the clinical syndrome.^{134,135}

Coronary artery aneurysms were described as early as the early 20th century, with a male to female ratio of roughly 3:1, including a male preponderance in childhood cases. Childhood death from multiple coronary artery aneurysms was known to occur at least as early as 1871, as reported by Samuel Gee.⁹⁰ The cardiac specimen from Gee's case, formalin fixed for more than 120 years in the pathology museum at St. Bartholomew's Hospital, London, recently was sectioned and examined histologically. The coronary arteries showed the characteristic histologic findings of inactive KD and IPAN.^{274,272} Whether these early cases with childhood coronary artery aneurysms truly represented early examples of KD is not certain; details of the clinical histories usually were scant.^{90,232}

What is clear, however, is that most of these cases greatly resemble (and very likely do, in fact, represent) KD.^{48,72,90,182,232} From the features of many such early case reports, a reasonably accurate picture of KD as recognized today emerges. It is highly likely that in the decades before the introduction of the measles vaccine in the 1960s, cases of KD were misdiagnosed as measles, scarlet fever, drug hypersensitivity, or other common conditions. In fact, an autopsy study of pediatric vasculitis cases in Japan indicates that many pediatric vasculitis fatalities prior to 1977 had clinical and pathologic features that in retrospect were consistent with KD.³⁰⁰ This study also demonstrated a marked decrease in all pediatric vasculitis fatalities in Japan following the advent of IVIG therapy in the late 1980s, suggesting that the majority of pediatric vasculitis fatalities in Japan prior to this time were actually the result of Kawasaki disease.³⁰⁰

Pathologic Features of Kawasaki Disease

Cardiac death in KD generally occurs in the subacute or convalescent stages of illness but also can occur earlier.^{186,189} KD results in medium-sized muscular arteritis, with a marked predilection for the coronary arteries.^{5,6,85,152,299,304,305} Small arterioles, larger arteries, capillaries, and veins also are affected to a lesser extent.^{6,84} In more than 80% of fatal cases in the acute stage, the immediate cause of death is acute thrombosis of inflamed coronary arteries, with resultant myocardial infarction. Less commonly, death can occur from acute coronary rupture, usually within a few weeks of the onset of illness, and rarely early deaths can result from pancarditis with inflammation of the atrioventricular conduction system and fatal arrhythmia or intractable congestive heart failure. Deaths that occur months to years after the acute episode of KD often are secondary to coronary stenosis, from luminal myofibroblastic proliferation (see below) and/or thromboses, resulting in myocardial ischemia. In some patients with coronary artery abnormalities (virtually always in those who also have quite severe coronary disease), aneurysms of other major medium-sized arteries, including the brachial, renal, and iliac arteries, also may be present. Although phlebitis may be found, vascular inflammation more typically and more severely affects medium-sized muscular arteries in their extraparenchymal portions. In the acute stage of KD, systemic inflammatory changes also are evident in many other organs, including myocardium, pericardium, cardiac valves, meninges, lung, lymph nodes, pancreas, spleen, joints, and liver.^{7,84,178}

An extensive study of arterial tissues from 32 patients who died and 8 who received heart transplants shed new light on the pathologic features of severely affected KD patients.²¹⁷ Three characteristic vasculopathic processes were identified by light and transmission electron microscopy: (1) acute self-limited necrotizing arteritis (NA), (2) subacute/chronic (SA/C) vasculitis, and (3) luminal myofibroblastic proliferation (LMP). NA is a neutrophilic process that starts at the endothelial lining of vessels only in the first 2 weeks of illness, progressively destroying the vessel wall and causing development of saccular aneurysms, which can thrombose or rupture. In its most severe form, NA can result in necrosis of arteries to such an extent that only a thin layer of adventitia remains. These “giant aneurysms” can rupture but more commonly acquire multiple layers of thrombi which organize and can become recanalized and calcify.^{5,192,217,260,295} SA/C vasculitis, consisting of lymphocytes, eosinophils, and plasma cells, with fewer macrophages, begins within the first 2 weeks of illness in the adventitia/perivascular tissue and damages the vessel wall during its progression toward the lumen. SA/C can lead to fusiform and saccular aneurysms that can thrombose, and it is associated with transition of medial and adventitial smooth muscle cells into smooth muscle cell–derived myofibroblasts which, with their matrix products, result in stenosing luminal lesions (SA/C-LMP). LMP can also occur in some areas without apparent local SA/C vasculitis.²¹⁷ NA is the only self-limiting of these three processes, is responsible for the earliest morbidity and mortality, and is consistent with acute viral infection. SA/C vasculitis can begin early but can persist for months or even years, whereas LMP can cause progressive arterial stenosis. Stenosis of the coronary arteries months to years after onset can result from LMP and/or thrombi.²¹⁷ The mechanism of persistent SA/C arteritis and LMP in a subset of KD children is unknown. Ongoing expression of vascular endothelial growth factor (VEGF) within smooth

muscle cells,²⁹⁶ TGF- β in myofibroblasts,²⁶⁵ and matrix metalloproteinases in inflammatory and other cells⁸⁹ have been proposed to be involved.

Significant atrioventricular conduction system lesions have been identified in 5 of 10 autopsy specimens, with a strong correlation found between ECG findings, especially PQ-segment prolongation, and acute inflammation of the atrioventricular conduction system.^{82,83} Severe acute changes were most pronounced at 21 to 31 days after onset. In a unique study of right ventricular endomyocardial biopsy specimens in 201 patients with uncomplicated acute KD, some degree of myocarditis and cellular infiltration ranging from very mild (subclinical) to quite severe myocardial inflammation was noted in all of the patients studied.^{351,352}

Neutrophils infiltrate the arterial wall at sites of NA; NA appears limited to the first 2 weeks after fever onset.²¹⁷ In SA/C arteritis, which begins in the first 2 weeks after fever onset but can persist for months to years in a subset of KD children, lymphocytes (particularly CD8⁺ lymphocytes²⁵), plasma cells (particularly IgA plasma cells^{253,255}), and eosinophils^{217,312} predominate, while fewer macrophages^{300,310} are also present. The transcriptome of KD SA/C arteritis demonstrates upregulation of genes associated with cytotoxic T-lymphocyte activation, antigen presentation, immunoglobulin production, and type I interferon response, features suggesting an antiviral immune response.²⁵⁶ Both CD8⁺ T lymphocytes⁴⁴ and IgA plasma cells have been demonstrated to be oligoclonal (i.e., they appear to be responding in an antigen-driven process).

Although arteritis is the most important pathologic feature of KD and results in the only known long-term sequelae of KD, the illness is associated with multisystem inflammation, and multiple organs and tissues are involved in the acute inflammatory process, including the digestive system (e.g., enteritis, hepatitis, cholangitis, pancreatitis), respiratory system (e.g., bronchitis, pulmonary nodules, segmental interstitial pneumonia), urinary system (focal interstitial nephritis, cystitis, prostatitis), nervous system (e.g., choriomeningitis), and hematopoietic system (e.g., lymphadenitis, splenitis), as well as the cardiovascular system (e.g., myocarditis, pericarditis).⁷ IgA plasma cells have been observed in peribronchial, pancreatic, and renal tissues²⁵⁵ and macrophages in pancreatic acini and islets.¹⁷⁸ Lymph node findings are nondiagnostic and can show severe lymphadenitis with necrosis.^{94,302}

At present, it is not known what factors predispose children with KD to develop coronary artery stenosis from LMP. This complication can occur in children with persisting aneurysms, but can also result in critical stenosis in patients with aneurysms that appear to have “resolved” by echocardiography or angiography. In this latter circumstance, arterial luminal diameter initially returns to a more normal range as LMP fills the lumen, but the lumen subsequently narrows with progressive LMP, and coronary artery blood flow is impaired. Close follow-up of all children with KD with persisting or “resolved” aneurysms is strongly encouraged, according to the recommendations of the American Heart Association Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease.^{171a,199}

CLINICAL MANIFESTATIONS

Clinical Phases of Illness

The clinical course of KD can be divided into acute, subacute, and late or convalescent phases. The *acute* febrile phase begins with fever, rash, conjunctival injection, “strawberry” tongue, red swollen lips, edema and erythema of the hands and feet, cervical lymphadenitis, and sometimes aseptic meningitis and mild hepatic dysfunction. Young children often are quite irritable. Evidence of myocarditis, rarely including congestive heart failure or arrhythmias, may develop during this time. Pericardial effusion, mitral regurgitation, and/or depressed myocardial function may be detected by echocardiogram. Without IVIG and aspirin treatment, the acute phase generally lasts 8 to 30 days (mean, 11 days).

After defervescence, the physical findings rapidly disappear, but, during this *subacute* phase, the child may remain irritable and anorectic, with decreased activity. Some conjunctival injection may persist. Arthritis or arthralgia, mainly of larger joints, may develop in the subacute phase. Desquamation of fingers and toes, typically beginning in the periungual region, and thrombocytosis are very common manifestations during this period. The subacute phase persists until the child has returned to

his or her normal state of health at 6 weeks after the onset of fever, with normalization of inflammatory markers. The time of greatest risk for sudden death occurring from acute coronary artery thrombosis in patients with coronary lesions is during the subacute phase and the early convalescent phase. The *convalescent* phase begins when all clinical signs and symptoms have disappeared and inflammatory markers are normal, usually at 6 to 8 weeks after onset.

In its complete form, KD is a distinctive clinical entity with a fairly predictable course.^{50,199} The principal clinical diagnostic criteria are presented in Box 77.1. A diagnosis of typical or classic KD, according to these accepted clinical criteria, is made in patients with fever and at least four of the five classic clinical criteria and with exclusion of other illnesses that mimic KD. Each of the five clinical features is present in 80% to 90% of patients with typical cases, except cervical lymphadenopathy, which is present in approximately 50% of patients. However, children who do not fulfill the classic criteria for diagnosis of KD, in fact, may have the illness and are at risk for developing complications, particularly coronary artery disease (see later discussion section on incomplete or atypical KD).^{199,251} KD should be considered in the differential diagnosis of infants and children with fever for at least 5 days associated with two or more of the five classic features: (1) generalized polymorphous erythematous rash, (2) conjunctival injection, (3) characteristic changes of the lips and mouth, (4) bilateral redness and swelling of the hands and feet, and (5) unilateral nonfluctuant cervical lymph node enlargement greater than 1.5 cm.¹⁹⁹ All features are not necessarily present at the same time. The most commonly encountered diseases to be excluded are febrile exanthems, presumably viral, including measles; acute streptococcal and staphylococcal infections; and drug hypersensitivity reactions. Japanese diagnostic guidelines for KD are similar to the U.S. guidelines with rare exception: they consider fever and the other five major features to be six equal criteria and require at least five of those six criteria for diagnosis.¹³ Thus a rare child could have no fever but all five other criteria and be considered a typical case by the Japanese criteria. The Japanese criteria also accept a course of fever lasting less than 5 days if it is shortened by early IVIG treatment.¹³

Several scoring systems using clinical and laboratory features have been developed, primarily in Japan.^{11,102,191} The initial goal of these systems was to identify those patients with KD at highest risk for development of coronary abnormalities and who, therefore, would benefit most from receiving IVIG therapy, as well as those at low risk for coronary changes who could be spared IVIG treatment. This practice has decreased in Japan because no such scoring system appears sufficiently sensitive and specific to enable selective therapy (i.e., to allow nontreatment of patients predicted to be at low risk for development of coronary abnormalities). More recent scoring systems have focused on identifying patients at high risk for IVIG treatment failure and coronary abnormalities who may benefit from more aggressive primary therapy.^{144,145} Patients who are at greatest risk are as follows: those younger than 1 year; male patients; those with prolonged or recurrent fever; and those with anemia, hypoalbuminemia, hyponatremia, and thrombocytopenia. The Kobayashi and other scoring systems are not effective in predicting treatment failure in multiracial populations as seen in the United States.^{144,277} All patients diagnosed with KD within the first 10 days after onset of disease and those diagnosed later who are still manifesting significant inflammation should be treated with IVIG and aspirin.¹⁹⁹

In KD, fever typically is high spiking and remittent, with peak temperatures generally exceeding 39°C (102.2°F) and in many cases exceeding 40°C (104°F). Unless treatment is initiated with IVIG and aspirin, fever persists for a mean of 11 days,¹⁰⁶ but it may continue for 3 to 4 weeks and rarely longer. In patients whose disease is treated with 80 to 100 mg/kg per day of aspirin and a single 2 g/kg dose of IVIG, fever generally resolves within 1 to 2 days.^{197,198}

Bilateral painless vascular injection of the bulbar conjunctivae, clearly more severe than injection of the palpebral conjunctivae and often sparing the limbic region around the cornea, generally is seen in the first week of illness, usually beginning shortly after onset of fever. It generally is not associated with exudate, conjunctival edema, or corneal ulceration, thus distinguishing the eye findings of KD from purulent conjunctivitis and from Stevens-Johnson syndrome. Mild acute

iritidocyclitis or anterior uveitis, which may be noted by slit lamp examination, resolves rapidly and only rarely is associated with photophobia or eye pain.^{28,91,154,210,279} Less common ocular findings include superficial punctate keratitis, vitreous opacities, vitreous and chorioretinal inflammation, lateral rectus palsy, and papilledema and other optic disk changes.^{8,76,114,336}

Changes of the mouth and lips consist of the following: (1) erythema, dryness, fissuring, peeling, cracking, and bleeding of the lips; (2) a strawberry tongue indistinguishable from that associated with streptococcal scarlet fever, with erythema and prominent papillae; and (3) diffuse erythema of the oropharyngeal mucosae. Oral ulcerations, pharyngeal exudates, and Koplik spots are rarely if ever found in KD and when present help to exclude the diagnosis.

Changes in the extremities are among the most distinctive features of KD. The hands and feet become indurated and swollen with stretched, shiny skin, sometimes with painful induration. The palms and soles become erythematous, often with an abrupt change to normal skin at the wrist and ankle. Infants and young children frequently refuse to hold objects or to bear weight. In the subacute phase, a distinctive pattern of periungual desquamation of fingers and toes may occur from 2 weeks to 2 months after onset of KD in 50% to 70% of affected patients. Beau lines, which are transverse grooves across the nails, may appear at the nail base 1 to 2 months after a case of acute KD and grow out over several months. Peripheral gangrene is a rare complication (see later discussion).

The erythematous rash associated with KD may take many forms. Most common is a nonspecific, diffuse, maculopapular, primarily truncal erythematous rash. Occasionally diffuse scarlatiniform erythroderma, urticaria, or an erythema multiforme-like rash with target lesions develops. Vesicles and bullae are not seen, although very fine pustules occur rarely. Perineal erythema and then desquamation are quite common manifestations in diapered as well as toilet-trained children in the acute stage of illness. Although rashes in KD tend to be most prominent on the trunk, with perineal accentuation they frequently also involve the face and extremities.

Cervical lymphadenopathy is the least common of the five principal diagnostic criteria, but it sometimes is the dominant clinical feature along with fever.²⁸¹ It usually is unilateral and confined to the anterior cervical triangle. To fulfill diagnostic criteria, the enlarged node or mass of nodes exceeds 1.5 cm, is not fluctuant, usually is not associated with erythema of the overlying skin, and is not tender or only moderately tender. Lymphadenopathy generally is benign and transient. Clinicians should be aware that children with suspected acute bacterial cervical adenitis that is unresponsive to antibiotic therapy may have KD. Because other features of KD often are present but overlooked, KD should be considered in such febrile children without an alternate diagnosis.²⁸¹ The ultrasound appearance of lymph nodes in KD has been described to be similar to that of acute Epstein-Barr virus infection and distinct from bacterial adenitis.³⁰⁶ The absence of changes suggesting suppuration on imaging (e.g., ultrasonography or computed tomography [CT]) of such lesions should strengthen the suspicion of possible KD in this setting. Impressive cervical adenopathy in patients with KD generally resolves remarkably promptly after administration of appropriate therapy.

The associated features of KD reflect its multisystemic nature (Box 77.2). Sterile pyuria as a manifestation of urethritis, occasionally with meatitis, is found in approximately half of patients. Arthritis appearing during the first week of illness can be polyarticular or oligoarticular, including the small interphalangeal joints as well as large weight-bearing joints, with a reported prevalence of approximately 7.5%.⁹⁷ Arthrocentesis during this early phase yields purulent-appearing fluid, with a mean white blood cell count of 125,000 to 300,000/mm³, normal glucose levels, and negative Gram stain and bacterial cultures. Arthritis developing after the 10th day of illness has a predilection for large weight-bearing joints, especially the knees and ankles, with a somewhat lower synovial fluid white blood cell count.¹⁰⁶ Gastrointestinal complaints occur in approximately one-third of patients, especially in older patients; these complaints may be severe, even leading to laparotomy, and they include nausea, abdominal pain, and some diarrhea. These findings may be related to a hydropic gallbladder, pancreatitis, or appendicular vasculitis.^{12,353} Obstructive jaundice and acute hydrops

Flare of atopic dermatitis or psoriasis
Peripheral gangrene (young infants)

of the gallbladder are not uncommon findings, whereas mild to moderate elevations of serum aminotransferases occur in almost half of patients. Central nervous system involvement including aseptic meningitis occurs in almost half of patients.⁵⁷ Transient unilateral lower motor neuron facial nerve palsy occurs rarely,²²⁸ as does sensorineural hearing loss.¹⁴³ Characteristic marked irritability is very common, especially in young infants. Reactivation of inflammation at the site of a previous bacillus Calmette-Guérin (BCG) vaccination coincident with acute KD is a common finding in Japan, where BCG is used widely,²⁷⁶ and Terp and associates observed a child in whom both a BCG site and a purified protein derivative (PPD) test site reactivated with acute KD.³¹³ Some patients experience a flare of atopic dermatitis or psoriasis during or after experiencing acute KD.^{24,68} Various pulmonary manifestations of KD, including isolated pulmonary nodules,⁸⁰ pleural effusions, acute respiratory distress syndrome,²²¹ and pulmonary infiltrates,³³⁰ all of which are interesting in view of the increased numbers of IgA plasma cells found in respiratory tract tissue,^{253,255} have been observed.

By far the most important associated feature of KD is *cardiac involvement*. Cardiac manifestations can be prominent in acute KD and are the major cause of long-term morbidity and mortality. In addition to the coronary artery abnormalities that develop in 20% to 25% of untreated children, pericardial effusion and myocarditis with congestive heart failure, tachycardia, gallop rhythm, nonspecific changes on the ECG, or arrhythmia may occur.^{123,126,128,199} An imperfect correlation exists between clinically apparent cardiac involvement and echocardiographic evidence of coronary abnormalities, although in the pre-IVIG era, echocardiographic evidence of mitral regurgitation, impaired left ventricular function, or pericardial effusion in the acute stage was shown to be predictive of subsequent coronary abnormalities.⁹² Echocardiographic evidence of perivascular brightness of coronary arteries was suggested as a criterion for early diagnosis of KD, but subsequent reports did not confirm the reliability of this finding as a useful sign of incomplete

KD.³⁵⁰ Acute KD may involve pericardium, myocardium, endocardium, coronary arteries, and cardiac valves. Clinical and auscultatory features may include a hyperdynamic precordium, tachycardia out of proportion for the child's age and temperature, a gallop rhythm, and a flow murmur. Some infants may manifest very low cardiac output, and ECG changes (ST-segment and T-wave changes, prolonged PR interval, and arrhythmias) may be present.

A relatively recently recognized unusual presentation of acute KD is hypotension or shock.^{63,122,161} Approximately 5% of patients may require admission to an intensive care unit for suspected septic shock or toxic shock but are ultimately recognized to have features of KD. In the few small series of cases, females and older patients have predominated, laboratory studies reveal more dramatically elevated markers of inflammation, and patients were more refractory to therapy compared with control subjects with KD. Hyponatremia was reported recently in a group of these patients, suggesting a possible association with the syndrome of inappropriate secretion of antidiuretic hormone.²⁷⁵

INCOMPLETE OR ATYPICAL KAWASAKI DISEASE

A substantial subset of children have illnesses that do not completely fulfill diagnostic criteria for KD but that include at least 5 days of fever and one, two, or three features of the disease. Incomplete or atypical KD (*incomplete* is the preferred term) is associated with a substantial risk for development of coronary artery aneurysms,^{22,86,158,199,251} but it can be very difficult to diagnose. Incomplete KD occurs most frequently in young infants, who unfortunately are at greatest risk for developing coronary disease with KD,^{242,251} and fatalities have occurred. The laboratory profile of incomplete cases is similar to that of classic cases, and laboratory results can increase or decrease the likelihood of the presence of KD in a particular patient.¹⁹⁹ Echocardiographic findings in the acute stage, including coronary ectasia, decreased myocardial contractility, pericardial effusion, and mild mitral regurgitation, can support the diagnosis of KD. Individual manifestations of KD in young infants tend to be more subtle than those in older children and can be fleeting.²⁴² KD should be considered in the differential diagnosis of prolonged fever in infants because patients are described in whom such fevers are virtually the sole manifestation of KD.

A committee of the American Heart Association developed a valuable algorithm to assist in the evaluation of patients with suspected incomplete KD (Fig. 77.1), with emphasis placed on clinical assessment and measurement of acute-phase reactants (CRP, ESR) in patients with 5 or more days of fever and two or three features of KD or in infants with 7 days or more of fever without other explanation.^{171a,199} In addition to elevated ESR (≥ 40 mm/h) and/or CRP (≥ 3.0 mg/dL), a set of six supplementary laboratory criteria that can be useful in this regard include albumin, 3.0 g/dL or less; anemia for age; increased alanine aminotransferase; platelets after day 7 of more than 450,000/mm³; white blood cell count of 15,000/mm³ or more; and 10 or more white blood cells per high-power field in the urine sample.^{199,171a} Hyponatremia is also useful in this regard. Echocardiographic features that support a KD diagnosis are Z score of left anterior descending (LAD) or right coronary artery (RCA) of 2.5 or greater, coronary aneurysm observed or three or more other suggestive features, including decreased LV function, mitral regurgitation, pericardial effusion, or LAD or RCA Z score of 2 to 2.5.

Retrospective diagnosis of KD often is based on finding coronary abnormalities on an echocardiogram, although the clinician's goal is to identify patients with incomplete KD before coronary changes have occurred. The existence of these patients again emphasizes the need to identify the etiologic agent of KD so that a diagnostic test can be developed. When possible, patients with illnesses suggesting incomplete KD should be referred to physicians with considerable experience in making the diagnosis.

LABORATORY FINDINGS

A specific diagnostic test for KD is not available and awaits discovery of the etiologic agent of the illness (Box 77.3). The laboratory features of KD, although quite nonspecific, are nonetheless characteristic of the illness. Leukocytosis, especially with neutrophilia, is typical in the acute stage, with a predominance of immature and mature granulocytes.

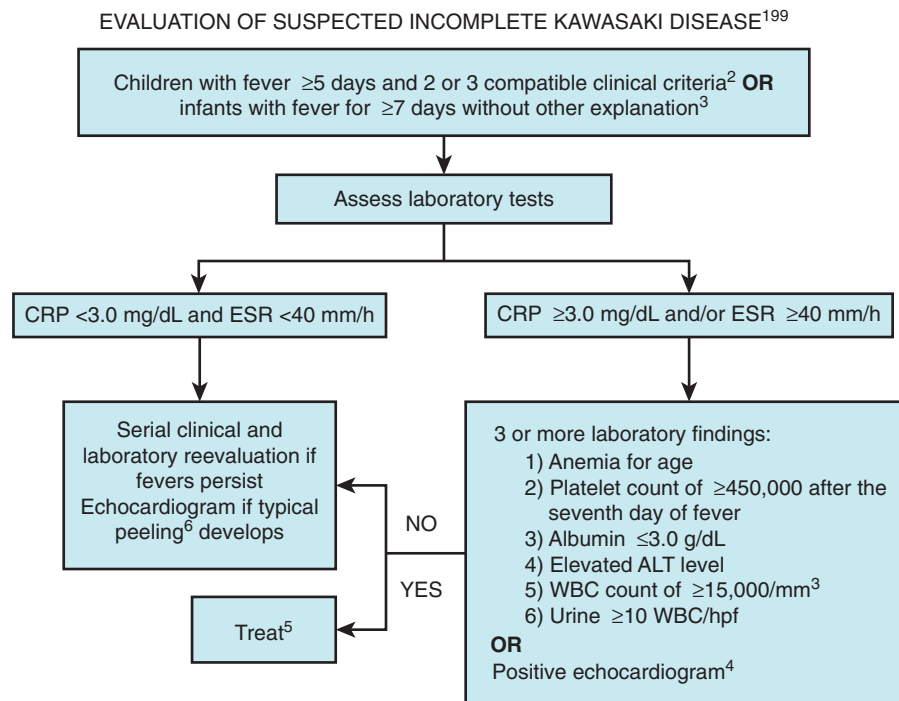

FIG. 77.1 Evaluation of suspected incomplete Kawasaki disease (KD). 1. In the absence of a gold standard for diagnosis, this algorithm cannot be evidence based but rather represents the informed opinion of an expert committee. Consultation with an expert should be sought any time assistance is needed. 2. Characteristics suggesting that another diagnosis should be considered include exudative conjunctivitis, exudative pharyngitis, ulcerative intraoral lesions, bullous or vesicular rash, generalized adenopathy, or splenomegaly. 3. Infants age ≤ 6 months are the most likely to develop prolonged fever without other clinical criteria for KD; these infants are at particularly high risk of developing coronary artery abnormalities. 4. Echocardiography is considered positive for purposes of this algorithm if any of three conditions are met: Z score of left anterior descending coronary artery or right coronary artery >2.5 ; coronary artery aneurysm is observed; or ≥ 3 other suggestive features exist, including decreased left ventricular function, mitral regurgitation, pericardial effusion or Z scores in left anterior descending coronary artery or right coronary artery of 2 to 2.5. 5. If the echocardiogram is positive, treatment should be given within 10 days of fever onset or after the tenth day of fever in the presence of clinical and laboratory signs (C-reactive protein [CRP], erythrocyte sedimentation rate [ESR]) of ongoing inflammation. 6. Typical peeling begins under the nail beds of fingers and toes. ALT, Alanine aminotransferase; hpf, high-power field; WBC, white blood cells. (From McCrindle BW, Rowley AH, Newburger JW, et al. Diagnosis, treatment, and long-term management of Kawasaki disease: a scientific statement for health professionals from the American Heart Association. *Circulation*. 2017;135(17):e927–e999.)

White blood cell counts in excess of $30,000/\text{mm}^3$ occur rarely, and those in excess of $15,000/\text{mm}^3$ occur in approximately 50% of patients. Leukopenia is unusual. Toxic granulations and Döhle bodies occasionally are seen on peripheral blood smear.²⁰ Anemia may develop, usually with normocytic red blood cell indices, particularly in patients with more prolonged duration of active inflammation. Severe hemolytic anemia requiring transfusions occurs but is unusual and usually is related to IVIG therapy.^{47,268} Curiously Kawasaki's first patient in 1961 (and only rare subsequent patients) manifested Coombs-positive hemolytic anemia.^{134,268}

Elevation of acute-phase reactants such as ESR, CRP, and α_1 -antitrypsin is nearly universal in KD. CRP values rise and fall much more quickly than do ESR values. Additionally, IVIG therapy per se leads to elevation of the ESR (but not CRP) for several weeks, and thus ESR is not useful in assessing the degree of inflammatory activity in IVIG-treated patients; CRP or other acute-phase reactants clearly are superior for this purpose.^{9,199}

A very characteristic feature of the subacute phase of illness is thrombocytosis, with platelet counts ranging from 500,000 to more than 1.5 million/ mm^3 . Thrombocytosis rarely is present in the first week of illness, usually appears in the second week, and peaks in the third week, with a gradual return to normal by 4 to 8 weeks after onset

in uncomplicated cases. The mean peak platelet count is approximately $700,000/\text{mm}^3$. In one study, infants younger than 1 year with fever without a source who had platelet counts greater than $800,000/\text{mm}^3$ were 17 times more likely to be diagnosed with KD ultimately than were infants with platelet counts lower than $800,000/\text{mm}^3$.²⁰³ No difference exists in chromium-65-labeled autologous platelet survival between cases and controls, and little correlation exists between thrombocytosis and increased platelet aggregation. The latter has been detected in patients with KD from a few days until a year after onset.^{131,337} The rare patients with thrombocytopenia in the acute stage of KD, most often young patients, are at increased risk for development of coronary artery disease and myocardial infarction.^{204,205} The mechanism of thrombocytopenia appears to be low-grade consumptive coagulopathy.²⁰⁵

Plasma lipids are markedly perturbed in acute KD, with depression of plasma cholesterol, high-density lipoprotein (HDL) cholesterol, and apolipoprotein A-I (apoA-I).^{37,194,259} Similar changes are observed in other conditions associated with an acute-phase response.³⁷ Marked appearance of serum amyloid A (SAA) protein in plasma, associated with HDL3-like lipoprotein particles, is seen acutely.³⁷ Cabana and colleagues³⁷ also showed that total cholesterol, HDL cholesterol, apoA-I, and triglyceride levels normalize over the course of several weeks and that SAA disappears from plasma. The core composition of HDL normalizes

BOX 77.3 Laboratory Features of Kawasaki Disease

Leukocytosis with neutrophilia
Elevated erythrocyte sedimentation rate
Elevated C-reactive protein (and other acute-phase reactants)
Anemia
Thrombocytosis after week 1
Sterile pyuria
Hypoalbuminemia
Hyponatremia
Elevated serum levels of aminotransferases and γ -glutamyltransferase
Plasma lipid abnormalities
Cerebrospinal fluid pleocytosis
Synovial fluid pleocytosis

more slowly than do plasma HDL cholesterol and apoA-I levels, a finding suggesting that KD has a profound effect on the lipoprotein profile acutely and a more subtle sustained effect on HDL composition.

Mild to moderate elevations in serum aminotransferase levels are present in as many as 40% of patients, and mild hyperbilirubinemia occurs in approximately 10%.³³ Plasma γ -glutamyl transpeptidase levels are elevated in most patients.³¹⁴ Hypoalbuminemia and hyponatremia are associated with more prolonged and more severe disease.^{102,153,275,332} Urinalysis reveals intermittent mild to moderate sterile pyuria in approximately one-third of patients, although suprapubic urine generally does not show pyuria, a finding suggesting urethritis.^{58,172} In those children who undergo lumbar puncture, evidence of aseptic meningitis, with a predominance of mononuclear cells, normal glucose, and normal to mildly elevated protein levels, is a common finding.⁵⁷

Laboratory tests, even though nonspecific, can provide diagnostic support in patients with clinical features that are suggestive but not diagnostic, of KD¹⁹⁹ and may aid in prediction of nonresponder patients, at least in Japan.¹⁴⁴ A moderately to markedly elevated CRP (>3.0 mg/dL) or ESR (>40 mm/h), almost universal in KD, is an uncommon finding in most viral exanthems and hypersensitivity reactions. Platelet counts higher than 450,000 mm³ usually are present in patients with KD after the seventh day of illness. In cases of incomplete KD associated with coronary abnormalities, thrombocytosis and elevated ESR/CRP are very common events in the acute stage. Clinical experience suggests that KD is unlikely if platelet counts and a full panel of acute-phase inflammatory reactants (e.g., ESR, CRP) are normal after the seventh day of illness.

Immunologic Findings

In the first 1 to 2 weeks of KD illness, marked peripheral blood neutrophilia is observed,¹⁹⁹ which coincides with the neutrophilic necrotizing arteritis that can occur in KD children who develop coronary arteritis.²¹⁷ Transcriptome studies of the peripheral blood in acute KD reveal neutrophil activation.^{229,230} This prominent neutrophilic innate immune response is accompanied by secretion of many proinflammatory cytokines and chemokines^{67,77} and abates as fever resolves, either spontaneously or in response to IVIG therapy. This response resembles that observed during many different infectious diseases associated with systemic inflammation and therefore has not been useful in establishing a specific KD diagnostic test. Nevertheless the presence of peripheral blood neutrophilia and elevated acute-phase reactants is so characteristic of KD that the absence of these findings argues against the diagnosis.

At 2 to 3 weeks after the onset of fever, elevation of all the immunoglobulins is observed in the peripheral blood,¹⁶² suggesting an acquired B-lymphocyte immune response. Beginning in the first 2 weeks of illness, subacute/chronic arteritis can be observed in medium-sized muscular arteries, especially the coronary arteries, characterized by infiltration of lymphocytes, eosinophils, plasma cells, and macrophages.²¹⁷ This process may occur in adjacent or nonadjacent regions of the arteries affected by necrotizing arteritis or in different arteries.²¹⁷ This infiltrate

is consistent with an acquired T- and B-lymphocytes immune response that appears to be oligoclonal or antigen driven.^{44,247,252} CD8 T cells are prominent in the coronary artery infiltrate,²⁵ and plasma cells in this infiltrate and in other inflamed KD tissues produce predominately IgA antibodies in the first month after fever onset,^{250,253} with IgM and IgG plasma cells present in lower numbers.²⁵³ In a subset of children with KD, subacute/chronic arteritis can persist for months to years.²¹⁷ It does not appear that autoantibodies are more prevalent in KD sera than in febrile childhood control sera.^{74,193} Circulating immune complexes can be detected in some KD patients but do not appear related to the development of coronary artery disease.⁷⁴

The arterial immune transcriptome of KD subacute/chronic arteritis is notable for activated cytotoxic T lymphocyte and type I interferon-induced gene upregulation, suggestive of an antiviral response, with no apparent dysregulation of the TNF- α gene family.^{254,256}

The stimulus resulting in these immunologic findings is likely to be a presently unidentified infectious agent(s). Whether the causative agent results solely in an antigen-driven immune response²⁴⁴ or can result in a superantigen response in some KD children^{170,349} is unclear and will likely require identification of the causative agent to be clarified.

The clinical response to IVIG treatment in KD patients generally is dramatic and rapid, and the majority of patients markedly improve during or immediately following completion of the infusion.^{197,198} The mechanism of action of IVIG in KD is unknown. Potential mechanisms include modulation of cytokine production, suppression of endothelial cell activation, or modification of T- and B-lymphocyte response or function.³¹ However, the very striking clinical response of KD patients to IVIG is unique and makes the theory of potential neutralization of a KD-specific agent or toxin or other product of the causative agent an appealing one.

In children with KD who do not develop cardiovascular sequelae, immune system function normalizes following resolution of the clinical signs, and inflammatory markers such as the CRP shortly after fever subsides. Although some investigators propose that many infectious agents may result in KD in genetically predisposed children,²⁹⁰ KD recurrence is actually quite uncommon,¹⁹⁹ and KD children appear to have normal responses to future infections without developing KD recurrences.

MANAGEMENT

Treatment During the Acute Stage

Initial Therapy

Patients diagnosed with KD should be admitted to hospital, undergo a baseline echocardiogram, and receive IVIG 2 g/kg over the course of 10 to 12 hours, with high-dose aspirin at 80 to 100 mg/kg per day in four divided doses as soon as practical (Box 77.4).^{50,199,273} When administered by the 10th illness day (onset of fever defines first day) this regimen is highly effective in reducing the risk for development of coronary abnormalities.¹⁹⁷ Because few data exist regarding management of patients treated later than the 10th illness day, the goal is to treat by illness day 10 whenever possible. Patients who are diagnosed after the 10th illness day and who are still febrile and/or with elevated inflammatory markers may benefit from therapy, but the ability to prevent coronary changes is less certain. IVIG and aspirin have been shown to prevent the development of giant coronary aneurysms^{46,249} and to have direct benefits on cardiac function.¹⁹⁵ The mechanism of action of IVIG in KD remains unknown.²⁶⁶ The single high-dose schedule is superior to the earlier regimen of 400 mg/kg/day IVIG for 4 days with high-dose aspirin with respect to rapidity of defervescence and normalization of acute-phase reactants, as well as in preventing development of coronary artery abnormalities.^{197-199,208} The large single-dose infusion generally is well tolerated, even in patients with decreased myocardial function.¹⁹⁵ Patients should generally remain hospitalized until they have been afebrile for at least 24 hours, to ensure that they are available for retreatment if necessary.

Whether treatment with IVIG and aspirin earlier than the fifth illness day leads to better or worse outcomes remains unclear. Some reports indicate fewer coronary abnormalities in those treated before the fifth³²² or sixth³⁵⁴ day of illness. Others report that those treated before day 5

BOX 77.4 Treatment of Kawasaki Disease**Acute and Subacute Stages**

IVIG 2 g/kg infusion over 10–12 hours *plus* aspirin 80–100 mg/kg per day in four divided doses (until patient is afebrile at least 3–4 days; some recommend until 14th illness day); then 3–5 mg/kg once daily for 6–8 weeks.

IVIG may be repeated if fever persists or recurs together with at least one classic sign of disease and/or elevated C-reactive protein level (see text and Box 77.5 for other alternative “rescue therapies”).

For patients thought to be at particularly high risk for development of coronary complications, an adjunctive course of corticosteroid may be considered, although the optimal dosing and duration are unclear.

Convalescent Stage

No coronary abnormalities: no therapy

Transient coronary abnormalities: aspirin 3–5 mg/kg once daily at least until resolution of coronary abnormalities

Persistent small to medium coronary aneurysms: aspirin 3–5 mg/kg once daily

Giant or multiple small coronary aneurysms: aspirin 3–5 mg/kg once daily, with or without clopidogrel 1 mg/kg/day, with warfarin or low-molecular-weight heparin for most patients

Coronary obstruction: thrombolytic therapy, surgical or interventional procedures

IVIG, Intravenous immunoglobulin.

were more likely to require additional therapy and/or have significantly worse coronary outcomes.^{69,76,188} A more recent study concludes that the observed higher risk for cardiac complications in those treated on illness days 1 to 4 are due to underlying greater initial disease severity enabling earlier diagnosis and that KD patients should be treated as early as possible.^{1a}

Single infusions of IVIG at doses of less than 2 g/kg have not been demonstrated to be as effective as 2 g/kg.^{14,70} Terai's comprehensive meta-analysis of all Japanese and North American IVIG treatment trials showed that the coronary artery outcome is correlated directly with the *total* dose per kilogram of IVIG, with 2 g/kg superior to 1.6 g/kg, which is superior to 1.2 and 1.0 g/kg; the initial dose of aspirin did not appear to influence coronary outcome.³¹¹ Another study confirmed this finding.⁶⁶

Patients diagnosed after the 10th illness day who are still febrile and/or who manifest other signs of active disease may benefit from IVIG and aspirin therapy because this treatment may result in prompt clinical improvement, with subsidence of fever and other signs of inflammation. Little evidence supports that this approach results in lower rates of development of coronary abnormalities, however. Patients beyond the 10th to 12th illness day who have become afebrile and have resolved their clinical features of KD without therapy are unlikely to benefit from IVIG. Such children should be treated instead with low doses of aspirin, 3 to 5 mg/kg once daily, and should be evaluated carefully by serial echocardiograms. In patients who have already developed coronary aneurysms and whose acute manifestations of illness and elevated inflammatory markers have resolved, there is no convincing evidence of a beneficial effect of IVIG.

Various preparations of IVIG differ in manufacturing processes and therefore in composition (e.g., the proportion of IgG monomers and the presence of proteins other than IgG). Although adverse reaction rates differ among products, clinical efficacy does not seem to differ.²⁴³ An exception is a report that showed IVIG prepared with β -propiolactone, which can affect the biologic activity of the Fc portion of IgG, to be less effective in KD.³²¹ Immunization with live virus vaccines such as for measles and varicella should be deferred for 9 to 11 months after administration of high-dose IVIG because of impaired immune responses.

The aspirin dosage for acute KD that is most thoroughly studied in the United States is 80 to 100 mg/kg per day in four divided doses. We

generally recommend that this be maintained long enough to ensure that the patient has been afebrile for at least 3 to 4 days and then reduced to a daily dose of 3 to 5 mg/kg for antiplatelet activity. Others often lower the aspirin dose earlier. The lower dose should be continued until 6 to 8 weeks after onset of illness in those who have not developed coronary abnormalities.¹⁹⁹ Patients who develop coronary abnormalities should continue to take low-dose aspirin. High-dose aspirin is used for its antiinflammatory activity, whereas the much lower dose inhibits platelet aggregation. Japanese clinicians generally use an intermediate antiinflammatory dose of 30 to 50 mg/kg per day because of perceived higher rates of untoward effects in Japan.^{13,150} Impaired absorption and bioavailability and enhanced salicylate clearance is present in acute KD.¹⁴⁶ Serum salicylate levels should be monitored only if symptoms of vomiting, hyperpnea, tinnitus, lethargy, or striking liver function abnormalities develop in children receiving aspirin.

A study that randomized U.S. patients to receive salicylates at 80 to 100 mg/kg per day or at 3 to 5 mg/kg per day for initial therapy (each regimen with 2 g/kg of IVIG) concluded that there was no difference in coronary outcome, but a more prompt clinical antiinflammatory benefit was noted in the high-dose aspirin group.¹⁷⁴ In the absence of IVIG, aspirin therapy does not decrease the frequency of coronary abnormalities.⁶⁶ Reye syndrome has been reported rarely in children taking high-dose aspirin for KD, but there are few data to suggest that low-dose aspirin poses this risk.²⁹⁸

Adjunctive Primary Therapy

The potential value of adding corticosteroid therapy to IVIG or aspirin for primary therapy has been addressed in several trials.^{145,196,207,236} For example, Jibiki and colleagues compared 3 days of intravenous dexamethasone 0.3 mg/kg per day plus heparin and IVIG, with subsequent low-dose aspirin, to IVIG plus higher dose aspirin and found more prompt decreases in fever and inflammatory markers in the dexamethasone-treated group but no difference in rates of coronary abnormalities.¹¹⁸ Okada and associates showed in high-risk patients that the addition of intravenous prednisolone (one pulse dose of 30 mg/kg) to IVIG and aspirin followed by a long taper of oral prednisolone was associated with shorter duration of fever, lower coronary abnormality rates, fewer treatment failures, and more a quicker fall in CRP and circulating interleukin-2 (IL-2), IL-6, IL-8, and IL-10 levels.²¹¹ Inoue and colleagues¹¹² compared 88 patients treated with IVIG and aspirin to 90 patients who received in addition intravenous prednisolone 2 mg/kg per day in three divided doses until afebrile and then orally until the CRP value normalized, with a subsequent taper over the course of 15 days, for a median of 23 days of corticosteroids.¹¹² The results indicated fewer coronary abnormalities, shorter durations of fever, more rapid decline in CRP level, and fewer initial treatment failures in the steroid recipients. Caution must be exercised in the interpretation of the findings of these Japanese trials because the IVIG regimens and aspirin doses usually differ from those used in the United States, and echocardiograms were not interpreted by investigators blinded to the treatment group. A well-designed US trial in this regard showed little if any direct benefit of the addition of a single dose of intravenous methylprednisolone 30 mg/kg to the current IVIG and aspirin regimen, with the possible exception of the subset of patients who failed to respond to standard therapy and who required retreatment of the disease.¹⁹⁶

Several attempts have been made in Japan to develop scoring systems to predict at the time of initial presentation those patients who are at increased risk for failure to respond to standard therapy^{69,144} and/or to develop coronary lesions after therapy.¹⁸⁰ In a retrospective analysis of 193 patients, Mori and colleagues found that elevated white blood cell and neutrophil counts and CRP levels after IVIG treatment predicted increased risk for subsequent development of coronary lesions.¹⁸⁰ Egami and associates compared 279 patients who responded to initial standard treatment to 41 patients who were treatment resistant.⁶⁹ With their scoring system giving one point each for month younger than 6 months, treatment before 4 days of illness, platelet count 300,000/mm³ or less, and CRP of 8 mg/dL or higher and two points for an alanine aminotransferase level of 80 IU/L or higher, a total score of three points or higher identified the IVIG-resistant group with 78% sensitivity and 76% specificity.⁶⁹ A similar predictive scoring system for IVIG

unresponsiveness was developed by Kobayashi and colleagues,¹⁴⁴ who gave two points each for initial treatment on illness day 1 to 4, serum sodium level of less than 133 mmol/L, aspartate aminotransferase value of 100 IU/L or higher, and neutrophils of 80% or greater and two points each for CRP of 10 mg/dL or higher, platelet count up to 300,000/mm³, and age 12 months or younger. This yielded 86% sensitivity and 67% to 68% specificity for patients with four or more points. The Kobayashi score was used to select patients at high risk for treatment failure in a randomized corticosteroid trial, as discussed earlier.¹⁴⁵

A more recent Japanese multicenter, randomized, open-label, blinded end points trial (the RAISE study) assessed the benefit of adjunctive primary steroid therapy for KD patients considered at high risk to be refractory to initial therapy.¹⁴⁵ Using the Kobayashi score¹⁴⁴ to identify patients at high risk for nonresponse to IVIG and aspirin, high-risk subjects were randomized to IVIG and aspirin (30 mg/kg per day until afebrile, then 3–5 mg/kg) or to IVIG, aspirin, and intravenous prednisolone 2 mg/kg per day for 5 days, converting to oral dosage once free of fever and then a 15-day corticosteroid taper beginning when the CRP level normalized. Significantly fewer recipients of corticosteroids developed coronary changes (3% vs. 13% at 4 weeks), and coronary z-scores were significantly lower in corticosteroid recipients. In another recent Japanese study,²⁰⁷ Ogata and colleagues evaluated corticosteroids with IVIG and aspirin 30 to 50 mg/kg per day in those patients with disease predicted to be refractory. Subjects were randomized to IVIG and aspirin alone or with a single 30 mg/kg dose of intravenously administered methylprednisolone and heparin from 2 hours before to 24 hours after the corticosteroid was given. Corticosteroid recipients had more rapid defervescence and decline in CRP levels with somewhat lower mean coronary z-scores ($z \geq 2.5$ in 9% of corticosteroid group, 38.5% in the noncorticosteroid group; $P = .04$), with transient adverse events only in the corticosteroid group.

It can be concluded that the addition of steroid to standard IVIG/ASA regimen in high-risk patients reduces the coronary abnormality rate and IVIG failure.

Unfortunately the Japanese scoring systems to identify high-risk patients are insensitive in ethnically diverse populations as seen in North America,^{277,318} and it is thus difficult to know how to target adjunctive therapy outside Japan.

A well-designed trial evaluated Infliximab (Remicade), a monoclonal anti-TNF- α antibody, as adjunctive primary therapy.³²⁰ The results showed safety but no significant benefit regarding IVIG resistance rates or rates of coronary artery abnormalities. Addition of infliximab for primary therapy with IVIG is not recommended.

Rescue Therapy for IVIG Treatment Failures

Most patients with acute KD respond promptly to treatment with IVIG and aspirin, with defervescence and subsidence of inflammatory manifestations occurring within 36 to 48 hours.^{197,199,267} A subgroup of 10% to 20%, however, fails to show significant clinical response; these patients remain febrile 36 to 48 hours after receiving IVIG or they manifest only transient improvement, with recurrent fever and clinical evidence of inflammatory signs and elevated CRP levels. These patients need additional antiinflammatory therapy, and specific guidelines or controlled treatment trials do not exist (Box 77.5). Of course, when treating apparently treatment-refractory patients, it is also prudent to reconfirm the initial diagnosis of KD.

In these patients, administration of a second dose of 2 g/kg of IVIG generally is effective in suppressing disease activity.^{80,104,199,275} In a retrospective study of 179 patients with KD, 89% responded to the first dose of IVIG and 67% of the nonresponders responded to a second IVIG dose; thus, only 3% to 4% of all patients failed to respond after a second dose of IVIG.¹⁰¹ Some recommend a course (usually 3 days) of intravenous pulse methylprednisolone at 30 mg/kg per day instead of a second dose of IVIG.³³⁴ We generally prefer to reserve pulse corticosteroid therapy for the patient with highly refractory acute disease who has failed to respond to at least two 2 g/kg doses of IVIG because most patients respond well to a second IVIG dose.^{101,131,177} No adequately powered randomized comparison between repeat IVIG dosing and corticosteroids for refractory patients has been performed. In a few particularly treatment-refractory patients, we have employed a slow

BOX 77.5 Rescue Therapy for Patients Not Responding to Standard Therapy

Persistent or recurrent fever and/or elevated serum CRP levels 36–48 hours after primary therapy:

- Repeat 2 g/kg IVIG
- Failure of two doses of IVIG: therapeutic options
 - Third dose of IVIG (2 g/kg) with or without tapering course of prednisone starting at 2 mg/kg¹⁴⁵
 - IV methylprednisolone (usually 30 mg/kg daily in three doses) with or without subsequent oral steroid, tapered over 1–3 weeks
 - Infliximab (5 mg/kg) single dose
 - Cyclosporin (4–8 mg/kg daily for 14–21 days), usually IV, with monitoring of serum levels and dosing adjustments
 - Methotrexate orally (10 mg/m²) \times 1–2 doses

CRP, C-reactive protein; IV, intravenous; IVIG, intravenous immunoglobulin.

oral corticosteroid taper over the course of weeks to several months once inflammatory activity appeared to have been controlled.

Infliximab has been reported in a nonrandomized open-label experience to be effective in most patients with acute KD who are refractory to standard therapy.²⁸⁰ Even more limited published experience exists regarding other therapies for IVIG-refractory KD. Cyclophosphamide with or without methotrexate has been used in a very small number of patients, as has plasmapheresis or plasma exchange.³³¹ Cyclosporine has been reported to be promising in this regard,²⁹¹ as has single-dose methotrexate.¹³⁹ Cyclosporine has been used for several weeks and requires assessment of blood levels and dosage adjustments.³¹⁹

Sequelae

The major (and virtually the only) sequelae of KD are cardiovascular, particularly coronary artery abnormalities. Therefore appropriate cardiac imaging is critical for the evaluation of patients suspected to have acute KD and for their subsequent follow-up. Echocardiography has been considered the ideal imaging modality because it is noninvasive and has high sensitivity and specificity for detection of abnormalities of the proximal left main, left anterior descending, circumflex, and right coronary arteries.¹⁹⁹ This procedure should be performed under the supervision of an echocardiographer experienced with evaluating children, and internal arterial diameters should be measured and compared with normal standards for body surface area, expressed as z-scores.^{60,167,199} The American Heart Association classifies coronary aneurysms as small (<5 mm), medium (5–8 mm), or giant (>8 mm); and de Zorzi and colleagues⁶⁰ and, more recently, Manliot and coworkers¹⁶⁷ showed that adjusting coronary dimensions for body surface area may identify more accurately those patients with enlarged coronary arteries. By z-scores, dilation is defined as a z of 2 to less than 2.5; a small aneurysm is defined as a z of 2.5 or more to less than 5; a medium aneurysm as a z of 5 or more to less than 10; and large or giant aneurysm as a z of 10 or greater or an absolute dimension of 8 mm or larger. Giant coronary aneurysms are associated with worse prognosis, and these patients require particularly close follow-up.^{46,199} The sensitivity and specificity of echocardiography to identify coronary thrombi and coronary stenosis are uncertain, and visualization of coronary vessels is more difficult as body size increases. Therefore angiography, magnetic resonance angiography (MRA),^{99,301} and ultrafast CT angiography (CTA)^{38,225} have been useful for selected patients with KD.^{199,262} Patients with significant coronary abnormalities are at risk for thrombotic events and are managed with antiplatelet agents and sometimes anticoagulants.^{117,199}

Management Beyond the Acute Stage

Patients with KD should be re-evaluated within 2 weeks after hospital discharge and again 6 to 8 weeks after onset of illness because echocardiography at these time points is most likely to detect coronary artery aneurysms should they develop. If a baseline study and these

two follow-up echocardiograms fail to detect evidence of coronary abnormality, performing further echocardiograms probably is unnecessary,³²⁶ although a 6- to 12-month follow-up echocardiogram is performed at many centers.^{51,199} Low-dose aspirin therapy (3–5 mg/kg per day) can be discontinued after the 6- to 8-week follow-up echocardiogram unless evidence of coronary abnormalities is present. To reduce the theoretical (and extremely low) risk for Reye syndrome in patients receiving low-dose aspirin, clopidogrel 1 mg/kg per day can be substituted for aspirin for a brief time in patients who develop varicella or influenza. Clopidogrel also can be used in the rare patient who is allergic to or intolerant of aspirin.

COMPLICATIONS

Myocardial Infarction

Myocardial infarction is the most common cause of death in KD (Box 77.6). In a classic cooperative Japanese study of 195 cases, the first myocardial infarction usually occurred in the first year after onset of disease and was fatal in 22% and asymptomatic in 37% of these patients. Major symptoms were shock, vomiting, and abdominal pain, with chest pain complaints only in children older than 4 years of age. Of those patients who survived a first infarct, 16% had a second myocardial infarct.^{125,127} Patients with giant (>8 mm or z-score >10) coronary aneurysms are at greatest risk for having infarcts, particularly related to thrombi and/or to stenotic areas adjacent to a giant aneurysm. Most fatal infarctions are the result of obstruction of the left main coronary artery or both the right coronary and left anterior descending coronary arteries; survivors are most likely to have isolated right coronary involvement. Approximately half the survivors of acute myocardial infarction had one or more complications, including ventricular dysfunction, mitral regurgitation, and arrhythmias. Parents of all children with KD with significant coronary abnormalities should be instructed to seek emergency medical care if chest pain, dyspnea, lethargy, or syncope develops. Prompt fibrinolytic therapy should be attempted at a tertiary care center if acute coronary thrombosis is diagnosed.^{124,199} The degree of reversibility of coronary thrombosis in children with KD may be somewhat less than that in adults with atherosclerotic disease. Late cardiac sequelae of KD may not manifest until adulthood.¹³⁰ A more recent Japanese study by Tsuda et al. assessed long-term outcomes of 60 KD patients who had a myocardial infarct between 1976 and 2007, with median follow-up of 16 years.³²³ The 30-year survival rate was 63% (95% CI, 45–78%) and the 25-year ventricular tachycardia-free survival rate was

29% (CI, 15–46%).³²³ Development of ventricular tachycardia was related to degree of nonviable myocardium.³²³

Other Cardiovascular Complications

Other cardiac complications include myocardial fibrosis, valvulitis, and coronary rupture. Some researchers have suggested that valvular disease occurs in as many as 1% of patients with KD; most of these cases result in significant mitral regurgitation.^{2,142} Patients with well-documented aortic regurgitation also have been observed. At least one patient with KD developed severe aortic and mitral regurgitation that necessitated double valve replacement.⁹³ In an autopsy study, coronary rupture was a rare finding but was noted more often among older children who died of KD within the first months after disease onset, whereas myocardial infarction was seen more often in younger fatal cases.²¹⁷

Peripheral artery aneurysms develop in fewer than 1% of patients with KD, virtually always in those who also have significant coronary abnormalities.^{132,294} These abnormalities generally involve medium-sized muscular arteries, such as subclavian, brachial, axillary, iliac, or femoral arteries and occasionally the hepatic or renal arteries or the abdominal aorta.

Peripheral Gangrene

A rare but very serious complication in the acute febrile stage of KD is severe peripheral ischemia and dry gangrene of distal extremities.³¹⁵ Virtually all such patients have been young infants up to approximately 7 months of age with giant coronary aneurysms, and some have developed peripheral (especially axillary or iliac) arterial aneurysms as well. This complication is virtually unknown in Japan¹³⁶ and has been reported primarily in non-Asian children in North America.^{65,315} Possible pathogenic mechanisms of peripheral gangrene include the following: severe arteritis of digital or other small peripheral arteries; arteriospasm of peripheral arteries, perhaps in association with severe vasculitis; thrombosis of inflamed or spastic arteries as a result of stasis and damaged endothelium; thrombosis of a more proximal aneurysm (especially axillary) with embolism distally; rarely, cardiogenic shock; and, most likely, a combination of these factors.^{291,309} This process has led to amputations in a small number of infants. Therapy has been empirical, primarily because the precise mechanisms of disease are unclear, and has included aggressive use of antiinflammatory agents; prostaglandin infusion; and antiplatelet, anticoagulant, and vasodilation therapies.^{65,315,333}

Nonvascular Complications

As many as 5% to 10% of patients with KD develop painful arthritis or arthralgia in the acute stage of disease, often in the ankles or other lower extremity joints that can persist for several weeks, and they may benefit from treatment with a nonsteroidal antiinflammatory agent. Earlier-onset arthritis (≤10 days of illness) tends to be polyarticular, whereas later-onset arthritis involves primarily larger weight-bearing joints. We have used naproxen, usually 10 to 15 mg/kg per day divided into two or three doses, for several weeks with considerable success. However, if an NSAID is used, the antiplatelet effect of aspirin is decreased, and an alternative antiplatelet agent (such as clopidogrel) should be given to patients at high risk of thrombosis.

Abdominal pain and diarrhea in the early acute stage usually respond to intravenous hydration and supportive care. Acalculous distention (hydrops) of the gallbladder manifests clinically as right upper quadrant tenderness or a mass with or without obstructive jaundice and can be confirmed by ultrasonography.^{199,284} Performing a cholecystectomy is not necessary. Hepatic involvement appears to be entirely self-limited and has not been associated with chronic liver disease.

Rare patients with KD develop hemophagocytic syndrome, also known as *macrophage activation syndrome*, as a complication.^{49,181,220} This syndrome manifests as persistent fever associated with cytopenias, hepatosplenomegaly, hepatic dysfunction, often hyperferritinemia, elevated serum lactate dehydrogenase, hypofibrinogenemia, and hypertriglyceridemia. Therapy with high doses of prednisone or other immune modifiers is indicated for this rare but serious complication.

Rare events that occur in association with KD include sensorineural hearing loss,¹⁴³ transient unilateral facial nerve palsy,^{88,228} and pneumonitis or pulmonary nodules.⁷⁹ We have cared for two older children who had

BOX 77.6 Cardiac Abnormalities in Kawasaki Disease

Acute Stage

Pericardial effusion
Decreased myocardial function
Mitral regurgitation
Enlargement (ectasia) of coronary arteries
Arrhythmia (rare)

Subacute Stage

Coronary aneurysms, irregularity, ectasia
Significant mitral or aortic regurgitation, or both (rare)
Coronary aneurysm rupture (very rare)
Myocardial infarction (rare)

Convalescent Stage

Persistent coronary aneurysms
Regressed coronary aneurysms (residual fibrosis)
Coronary artery stenosis
Coronary aneurysm rupture (very rare)
Myocardial infarction (rare)

sufficient abdominal findings to warrant appendectomy before establishing the diagnosis of KD. Consultation with a center that treats large numbers of patients with KD should be sought by the physician faced with patients with rare or serious complications.

LONG-TERM FOLLOW-UP AND PROGNOSIS

KD normally is an acute and self-limited illness. However, cardiac abnormalities that develop when the disease is active may be progressive, and prognosis clearly is related to the coronary artery status.¹¹⁷ Twenty to 25% of patients not treated with IVIG develop coronary abnormalities that are detectable by two-dimensional echocardiography or angiography. The risk for development of coronary aneurysms is reduced to 2% to 3% overall when IVIG is given in the first 10 days of illness.^{197,198} However, the rates for coronary abnormalities for young infants are somewhat higher, even with timely IVIG therapy. The risk for significant coronary events such as thrombosis, stenosis, myocardial ischemia, myocardial infarction, and even sudden death is correlated with higher coronary z-scores for many years after onset of illness and into adulthood.^{127,171,199}

Children without apparent cardiac sequelae during the first month after onset of KD appear to return to their previous states of health without cardiac signs or symptoms. However, some reports suggest the possibility of generalized vascular endothelial dysfunction in patients with KD even in those who never had coronary abnormalities. These dysfunctions include altered lipid metabolism,³⁷ increased brachial-radial artery mean pulse wave velocity,⁴³ lower myocardial flow reserve,¹⁸⁵ and abnormal endothelium-dependent brachial artery reactivity,^{61,176,201,338} but the data are not consistent and additional studies are needed.

Apparent “regression” of small and medium aneurysms as seen on an echocardiogram is a common occurrence. Overall, approximately half of all children with coronary aneurysms at 4 to 8 weeks after onset demonstrate normal luminal size by 1 to 2 years on angiography or echocardiography.^{125,128} The likelihood that an aneurysm will appear to regress by echocardiography or angiography is higher with smaller aneurysms, age younger than 1 year at the onset of KD, fusiform rather than saccular morphology, and involvement of a more distal coronary segment.^{4,297} “Regression” of the internal diameter of the vessel to normal may occur by luminal smooth muscle cell–derived myofibroblastic proliferation and/or by thrombus organization and recanalization.^{85,217,260,273} Intravascular ultrasound studies have been interpreted to suggest that thickened intima and media sometimes with calcifications are present in areas of apparently regressed coronary aneurysms.^{100,286} However, direct correlation of intravascular ultrasound findings and histology has not been performed. A recent histologic study of 41 heart specimens demonstrated that calcification was found only in areas of organized thrombus not in vascular media or intima.²¹⁷ Regressed aneurysmal segments are histologically abnormal and have abnormal functional responses with decreased vascular reactivity to exercise or pharmacologic agents such as isosorbide dinitrate or acetylcholine,^{61,110,260} with the potential to progress to stenosis.^{129,293,295}

Functional abnormalities of coronary vessel endothelium relaxation years after the onset of KD have been reported^{61,110,176} and warrant further investigation. Newer imaging methods have demonstrated coronary vascular wall changes sometimes even in patients with no history of abnormalities in the acute phase. The meaning of these findings in patients thought to have escaped coronary abnormalities with acute KD and their long-term significance are uncertain.

Patients with giant coronary aneurysms are at the greatest risk for the development of significant stenosis with resultant myocardial ischemia.^{117,132,199,283} The risk for significant stenosis, usually developing at the inlet or outlet of a moderate to large coronary aneurysm, shows a steady rise over 15 to 20 years of observation.^{121,132,283,293} These markedly abnormal vessels are subject to luminal fibroblastic proliferation, calcification, and thrombosis, which may lead to myocardial ischemia or infarction. An analysis of 76 subjects with giant aneurysms from one Japanese center with median follow-up of 19 years showed 95%, 88%, and 88% 10-, 20-, and 30-year survival rates, respectively. Catheter and surgical coronary interventions resulted in 28%, 43%, and 59% cumulative coronary intervention rates at 5-, 15-, and 25-year follow-up, respectively.²⁸³

In 10- to 20-year follow-up studies of patients with KD, the arteries most likely to develop stenosis are the right main and left anterior descending coronary arteries.^{121,132,283} A limited number of studies of young adults with ischemic heart disease and history of diagnosed KD or a compatible clinical illness have been performed.^{53,130} A survey of Japanese adult cardiologists identified 130 adult patients with coronary aneurysms detected by angiography to evaluate myocardial infarction or ischemia.¹³⁰ Twenty-one of these patients (mean age, 34 years; range, 20–63 years) had a history compatible with KD in childhood. These patients had severe coronary disease with myocardial infarction, angina pectoris, mitral regurgitation, arrhythmias, congestive heart failure, and need for coronary bypass grafting. This study indicates that the coronary artery sequelae of KD likely are significant causes of ischemic heart disease in young adults. Daniels and coworkers evaluated 261 adults younger than 40 years who underwent angiography for suspected myocardial ischemia and found 16 with coronary aneurysms, 13 of whom had definite or presumed KD as the cause.⁵³ It is unknown whether patients with KD are at increased risk for developing premature or accelerated atherosclerosis, but there are no data to support this.

Long-Term Management

The risk for coronary artery thrombosis or stenosis that may result in myocardial ischemia and infarction remains the most important long-term clinical problem in the subset of patients with KD who develop significant coronary abnormalities (see Box 77.6). Patients classified as having medium (6–8 mm, or z ≥ 5 to <10), and large and giant (≥ 8 mm, z ≥ 10) aneurysms are at substantial risk for development of stenosis years after the acute illness, compared with patients with small aneurysms (z <5) or no aneurysmal changes.^{4,121,125,128,132,294,325} Patients with giant aneurysms are at the highest risk for thrombosis.¹⁹⁹ Manlhiot and colleagues¹⁶⁷ documented that the previous American Heart Association classification scheme noted earlier underestimated the severity of coronary abnormalities and showed the following optimal definitions: small aneurysm, z-score of 2.5 to less than 5.0; medium aneurysm, z-score greater than or equal to 5.0 to less than 10.0; and large and giant aneurysm, z-score greater than or equal to 10.0. Echocardiography and electrocardiography often are not sufficiently sensitive to detect stenotic lesions. Various stress tests for detection of reversible myocardial ischemia, including nuclear perfusion scans with exercise, exercise echocardiography, and stress echocardiography with agents such as dobutamine, dipyridamole, or adenosine, have been used in children to detect stenosis.^{199,206,219} Newer techniques, including stress magnetic resonance imaging (stress MRI), MRA, CTA, and position emission tomography (PET) are being utilized.^{38,99,225,301} Coronary arteriography has been the most definitive method to determine the degree of stenosis and the adequacy of collateral circulation but is invasive. Intravascular ultrasonography is an effective method to evaluate vascular wall morphology in selected patients during angiography.^{287,292} All patients with evidence of myocardial ischemia or infarction should be studied by angiography to determine the need for intervention.¹⁹⁹ Most experts agree that patients with moderate to severe coronary artery aneurysms, a single large aneurysm, or multiple aneurysms should have their coronary anatomy defined by angiography or MRA or CTA at least once after the acute stage of illness (after the inflammatory process has subsided) to define fully the extent of involvement and to identify potential sites of thrombotic or stenotic complications.¹⁹⁹ Aneurysms can also occur in non-coronary arteries, especially the subclavian, brachial, axillary, iliac, and femoral arteries, and occasionally in the abdominal aorta and renal arteries²⁹⁴ (almost always in patients with coronary abnormalities).

Because KD patients with past or present aneurysms variably have evidence of chronic inflammation and reduced HDL-cholesterol levels, some have suggested that HMG CoA-reductase inhibitors (statins) may be beneficial. In addition to their LDL-cholesterol lowering effect, statins have potentially beneficial pleiotropic effects on inflammation, oxidative stress, endothelial function, platelet aggregation, fibrinolysis, and coagulation. Small short-term studies in KD patients with aneurysms showed improved endothelial function and lower hs-CRP levels. Safety studies have not identified an effect on growth. Empiric low-dose statin may be considered in KD patients with past or current aneurysms.²⁰²

Patients who have had KD are risk stratified into five levels based on their relative risk of myocardial ischemia and coronary z-scores for long-term management by the American Heart Association, as outlined here.¹⁹⁹ The American Heart Association recommendations should be consulted for more details^{171a}.

Patients With No Evidence of Coronary Artery Abnormalities at Any Time (Risk Level I)

Patients who have never manifested coronary artery abnormalities (z always <2) have no need for aspirin or other antiplatelet medication beyond 6 to 8 weeks after onset of illness or for restriction of physical activities in the convalescent stage. Only routine pediatric follow-up beyond 1 year, with routine cardiovascular risk assessment, is indicated.

Patients With Dilatation (z ≥ 2 but <2.5, or >1 Decrease in z During Follow-up; Risk Level II)

Patients with transient coronary artery abnormalities that resolve by 6 to 8 weeks should be treated with aspirin 3 to 5 mg/kg per day until resolution of abnormalities. No restrictions are indicated after 6 to 8 weeks, angiography is not indicated, and risk assessment and counseling are recommended at 2- to 5-year intervals.²⁸⁵

Patients With Small (≥ 2.5 to <5) Coronary Aneurysm in One or More Coronary Arteries (Risk Level III)

Patients with small coronary artery aneurysms should be maintained on daily low-dose aspirin (3 to 5 mg/kg) at least until apparent regression is documented with annual echocardiographic follow-up.²⁸⁵ No restriction on physical activity is indicated, and assessment for inducible myocardial ischemia should occur every 2 to 5 years depending on presence of symptoms of ischemia or ventricular dysfunction.

Patients With Medium Aneurysms (z-score ≥ 5 to <10, with Luminal Dimension <8 mm; Risk Level IV)

Long-term antiplatelet therapy with low dose aspirin 3 to 5 mg/kg once daily or clopidogrel 1 mg/kg per day up to adult dose of 75 mg is indicated for these children and should be continued indefinitely. Anticoagulant therapy with warfarin or daily subcutaneous low-molecular-weight heparin is not usually warranted. All such patients should be under the care of a physician with experience in managing patients with KD, usually a pediatric cardiologist. Cardiac evaluation with an echocardiogram and an ECG should be performed approximately every 1 to 2 years depending on persistence or return to normal luminal diameter, with stress testing performed every 1 to 4 years. Angiography may be considered 6 to 12 months after the patient has recovered from the acute stage of disease to define the coronary anatomy, and it should be repeated whenever symptoms or stress tests suggest the presence of myocardial ischemia. Physical activity should be regulated if receiving more than a single antiplatelet agent, and competitive sports should be based on periodic stress testing.

Patients With Large and Giant Coronary Artery Aneurysms (z-score ≥ 10 or ≥ 8 mm) and/or Obstructive Lesions (Risk Level V)

These patients should receive low-dose aspirin and/or clopidogrel as well as anticoagulation with either warfarin or low-molecular-weight heparin, and they require very close cardiac care with periodic stress testing to guide participation in physical activity. Patients with obstructive lesions or signs of myocardial ischemia must be evaluated urgently for possible intervention. Balloon angioplasty, rotablator angioplasty, coronary artery bypass grafting, stent placement, and even cardiac transplantation all have been employed for patients with KD who have particularly serious coronary artery disease.^{3,41,98,113,183,324} Arterial bypass grafts are superior to venous grafts in these patients.¹⁴¹ Balloon angioplasty procedures have been associated with high rates of recurrent stenosis in patients with KD and coronary stenosis.³ Management details for this group of patients are beyond the scope of this chapter.

Chronic Fatigue Syndrome (Systemic Exertion Intolerance Disease)

78

Leonard R. Krilov

All cases are unique and very similar to others.

T.S. Eliot, *The Cocktail Party*, 1949.

Chronic fatigue syndrome (CFS) is an illness complex characterized by a prolonged (>6 months) period of constant or intermittent debilitating fatigue in association with multiple, often nonspecific, symptoms that may include new-onset headaches, decreased ability to concentrate, recurrent complaints of sore throat and tender cervical or axillary lymphadenitis, reports of low-grade fever, diffuse muscle or joint pain, postexertional increase in fatigue, and unrefreshing sleep. To date, no specific cause for this syndrome has been identified, and, despite similar arrays of signs and symptoms, patients with CFS likely represent a heterogeneous population. Still, evaluation of groups of patients with this symptom complex has provided information about pathophysiologic changes occurring in patients with CFS, and potentially beneficial, although not curative, approaches to therapy for affected individuals have been developed.

In an attempt to provide a degree of uniformity as a basis for research into the evaluation of such patients, the US Centers for Disease Control and Prevention (CDC) developed a definition of CFS in 1988.⁵¹ These criteria were revised in 1994, with physical signs removed from the definition because they appeared to be unreliably documented in studies and the required number of symptoms for the diagnosis of CFS decreased from 8 of a list of 11 to 4 of 8 components (Box 78.1).⁴² These changes, being less restrictive, may serve to increase the sensitivity of the diagnosis, but they also decrease the specificity. However these criteria are purely speculative in the absence of any gold standard or definitive diagnostic test for CFS. These 1994 criteria also suggest subdivisions of patients with CFS for research purposes and provide guidelines for nonresearch clinicians as well. Other international groups have generated similar definitions of CFS for evaluating this condition.^{16,71,101}

The primary manifestations of CFS are severe fatigue of more than 6 months' duration that limits activity to less than 50% of premorbid function and the association of multiple other symptoms, as outlined in the case definitions of CFS.^{42,51,71,101} These symptoms include new or more intense headaches, decreased ability to focus or concentrate, recurrent sore throats, a sensation of tender cervical or axillary lymph nodes, low-grade temperature elevations, myalgias and arthralgias, postexertional fatigue lasting longer than 24 hours, and sleep disturbances (hypersomnia or insomnia). The severity and persistence of these findings vary among individual patients with CFS. In addition, although not included in the case definitions, many patients report dizziness, especially with changes in position, feeling hot when others are cold or vice versa, chronic costochondritis, and a Raynaud-like phenomenon.

In 2015, the Institute of Medicine (IOM) recommended renaming the syndrome systemic exertion intolerance disease (SEID) in an effort to emphasize that any exertion (physical, cognitive, or emotional) can lead to adverse effects in these patients. This definition requires that patients have:

1. A substantial reduction or impairment in the ability to engage in premorbid levels of activities persisting for more than 6 months

and be associated with new-onset fatigue that is not alleviated by rest.

2. Postexertional fatigue.
3. Unrefreshing sleep.

Additionally this definition includes the presence of cognitive impairment and/or orthostatic intolerance.^{21,53}

HISTORICAL OVERVIEW

In all likelihood, CFS is not a new illness. Numerous conditions with features comparable to those of CFS have appeared in the medical literature during the past several centuries.¹¹⁵ Many of these descriptions attempted to associate an illness characterized by prolonged debilitating fatigue and numerous other symptoms with an infectious agent. They have included chronic brucellosis,¹⁰⁸ chronic enteroviral syndrome,^{23,29,46} chronic candidiasis,⁹⁴ myalgic encephalomyelitis,² chronic mononucleosis (Epstein-Barr virus [EBV] infection),^{4,54,120,121} human herpesvirus-6 infection,^{11,129} human herpesvirus-7 infection,³⁴ chronic Lyme disease,¹⁰⁹ parvovirus B19 infection,⁶⁰ and a new retroviral infection.³¹ Noninfectious conditions described with similarities to CFS include total-allergy syndrome, hypoglycemia, neurasthenia, Iceland disease, Royal Free disease, and fibromyalgia rheumatica.⁶⁴ In addition to clinical similarity to CFS, all these conditions, at least at the time they were described, lacked a diagnostic test to confirm a definitive causative agent and, in their acute form, manifested as fatigue in association with multiple other complaints.

A review of the experience in the mid-1980s associated groups of patients with CFS-like illness with patients with chronic EBV infection.^{4,54,120} These reports described elevated and aberrant patterns of EBV antibody responses in individuals with prolonged fatigue and multiple symptoms consistent with CFS. Acute infectious mononucleosis also often manifests as fatigue, fever, malaise, sore throat, lymphadenitis, and multiple systemic complaints, although typically in a more pronounced manner. Subsequent studies, however, revealed that the elevation or pattern of EBV antibody responses in such patients was not consistently different from findings in others who resolved symptoms of acute EBV infection.⁷⁹ Additionally shedding of EBV in secretions was not increased in these individuals, and no association was found between viral shedding and severity of symptoms.¹²² Furthermore no response to the antiviral drug acyclovir occurred in a group of such patients in a placebo-controlled, double-blind crossover study in terms of improvement of clinical symptoms.¹¹⁷ After these observations were made, the name *chronic fatigue syndrome* was chosen to define this illness,⁵¹ at least until a specific cause or marker for this illness is identified.

Cameron and colleagues reported on a cohort of patients with prolonged fatigue after having infectious mononucleosis. No difference in EBV load was demonstrated in eight patients with 6 months or more of disabling symptoms after the diagnosis of infectious mononucleosis was established, and again there was a lack of correlation between persistent symptoms and viremia or altered host responses to EBV.¹⁴

BOX 78.1 Centers for Disease Control and Prevention 1994 Workshop Case Definition of Chronic Fatigue Syndrome

1. Fatigue (persistent or relapsing) that has new or definite onset, is of greater than 6 months' duration, and leads to a substantial (>50%) reduction in level of activity
plus
2. At least four of the following:
 - Impaired memory or concentration
 - Sore throat
 - Tender lymph nodes: cervical or axillary
 - Myalgias
 - Arthralgias (multiple joints, without swelling or erythema)
 - New onset (or in severity) of headaches
 - Unrefreshing sleep (hypersomnia or insomnia)
 - Postexertional fatigue lasting more than 24 hours*and*
3. The absence of another diagnosis for the individual's signs and symptoms

Modified from Fukuda K, Straus SE, Hickie I, et al. The chronic fatigue syndrome: a comprehensive approach to its definition and study. *Ann Intern Med.* 1994;121:953–9.

Despite the lack of association of ongoing EBV infection with CFS, Katz and colleagues observed that infectious mononucleosis may be an antecedent risk factor for CFS in adolescents.⁵⁹

Recently increased detection of nucleic acid of a xenotropic murine leukemia virus (XMRV), a newly discovered retrovirus, was reported in two different series of CFS patients.^{73,74} Subsequent studies failed to confirm these observations, including two reports that utilized samples from the same patients reported in the two positive studies just cited.^{5,50,104,124} Contamination of the assays in the positive studies may have been responsible for the positive results, and both of those studies were subsequently retracted.^{3,48,103}

EPIDEMIOLOGY

The definitions of CFS allow for attempts to characterize the prevalence and demographic features of this condition. Still, given the vagaries of the symptom complex, possible variations in application of the diagnosis by different health care providers, and the potential differences within groups of people to seek medical attention for this condition, data reported on these issues may not be a complete representation of the epidemiology of this condition. CFS has been reported in all age groups, including children as young as 5 years of age, and in all ethnic, racial, and socioeconomic groups, but most CFS cases have been reported to occur in middle- to upper-class white women with a median age of 35 to 40 years.⁶³ Based on a study of physician-diagnosed patients from four cities using the 1988 case definition of CFS,¹ the CDC estimates a minimum prevalence rate of CFS of 2 to 10 cases per 100,000 or higher in adults aged 18 years and older in the United States.^{12,76,91} A population-based descriptive epidemiologic study conducted by the CDC in Kansas estimated the prevalence of CFS to be 235 per 100,000 persons and a 1-year incidence to be 180 per 100,000 persons.⁹⁵ Studies from outside the United States have reported similar or higher prevalence rates of CFS in adults.^{35,71}

Although the CDC definition does not include age criteria for the diagnosis of CFS, the prevalence of CFS in the pediatric age range has not been studied well. Some researchers have suggested that the diagnosis of CFS should not be used in children to avoid potential delay in making an alternative medical or psychological diagnosis.⁹⁰ However many referral centers have reported groups of pediatric patients, primarily adolescents, with features and a clinical course similar to those reported in adults.^{6,17,36,66,77,106} Furthermore in these studies, missed or alternative diagnoses were not found, despite years of follow-up. Rimes and

TABLE 78.1 Symptoms Reported by 58 Children and Adolescents Evaluated for Chronic Fatigue Syndrome (1989–94)

Symptom	No. Patients	%
Fatigue	58	100

Depression	4	7

From Krilov LR, Fisher M, Friedman SB, et al. Course and outcome of chronic fatigue in children and adolescents. *Pediatrics.* 1998;102:360–6.

colleagues reported prevalence rates of CFS in an adolescent population similar to those reported in adults.⁹⁶ The CDC estimates that between 0.2% and 2.3% of children or adolescents meet the diagnostic criteria for CFS, with the condition more prevalent in adolescents than younger children.¹⁹ Collin and colleagues similarly estimated a prevalence of CFS at 1.86% in a population-based study of 16-year-olds, as reported by their parents.²⁴ In these pediatric studies, a predominance of female patients with a median age of 14 years at the time of diagnosis was noted. Additionally these patients were from predominantly middle- to upper-class families, and, as discussed later, their signs and symptoms at presentation (Table 78.1) and their course of illness were similar to those reported in adults with CFS. CDC studies suggest that the prevalence of CFS in adolescents approaches that reported in adults, but cases in children younger than 12 years of age occur much less often.⁴² One suggestion is that a shorter duration of symptoms (3 to 4 months vs. 6 months) may be appropriate for establishing the diagnosis of CFS in pediatric patients.^{42,55} Multiple family members with CFS may be seen as well, but, to date, evidence that CFS is contagious does not exist. Most often in this setting it is mothers of adolescents with CFS who exhibit similar symptoms.¹²⁶

ETIOLOGY AND PATHOGENESIS

Infection

As noted previously, an infectious origin of CFS has not been demonstrated, and a single microorganism as the cause of CFS is unlikely. However an acute infection appears possibly to play a role in precipitating CFS because most (as many as two-thirds) patients with CFS relate a sudden onset of their symptoms to an acute infection, most often infectious mononucleosis. Lyme disease^{75,109} and an influenza-like illness⁵² also have been reported in association with the onset of CFS.

Immunologic Dysfunction

A role for immunologic dysfunction in CFS has been suggested based on numerous studies demonstrating abnormalities in lymphocyte

function or cytokine production.^{13,62,69,80,116,119,123} However these findings have not been reproducible in different groups of patients with CFS. Some evidence suggests that nonspecific elevation of antibody titers and an increase in allergic symptoms occur in patients with CFS.¹¹⁸ However these findings are mild, and similar immunologic changes may be seen in other conditions, including depression. Individuals with CFS may report an increased frequency and duration of infections compared with their pre-CFS state, but they tend to be mostly routine viral illnesses. Neither unusual nor opportunistic infection nor increased risk for developing malignant disease has been observed in these individuals. Intravenous immunoglobulin infusions have not demonstrated long-term clinical benefit when they are administered to patients with CFS and may cause significant adverse reactions.^{72,89,114}

Genetic Components

A number of recent studies of gene expression from peripheral blood samples have identified potential gene patterns associated with neuroendocrine function, stress reactions, and immune responses that may be associated with CFS.^{49,61} Further definition of such genes may help further establish a biologic basis for development of CFS and eventually lead to diagnostic tests for CFS and targeted approaches to therapy.

Some studies have focused on potential genetic markers of CFS using DNA microarray technology.¹¹⁰ An analysis of cytokine gene polymorphisms in 80 Italian patients with a diagnosis of CFS assessed using the 1994 CDC definition reported significant difference in tumor necrosis factor and interferon- γ phenotypes compared with controls. The authors hypothesized a potential altered immunologic or inflammatory response based on these differences as potentially contributing to the pathogenesis of CFS.^{10,15,39} An analysis of prolonged postinfectious fatigue in patients who had had mononucleosis identified certain genes involved in immune responses, and hormonal and neurologic pathways that were altered in a subset of patients with mononucleosis were associated with the development of prolonged fatigue.^{14,45,107} If reproducible gene expression markers are confirmed, they could potentially be used as diagnostic tools for CFS.

CLINICAL MANIFESTATIONS

Neurologic Factors

Many patients with CFS report cognitive impairment manifest as a decreased ability to concentrate and focus, difficulty in processing information, and trouble with word recall. Complaints of headache (new onset or altered pattern) and other neurologic symptoms, such as paresthesias and dysequilibrium, also are reported commonly by patients with CFS.

Despite these complaints, physical examination does not reveal abnormal neurologic signs. Formal neuropsychometric testing also may not reveal objective abnormalities to the extent reported by the patient. Whether this discrepancy reflects a problem with testing methods or altered perception on the part of the individual is uncertain at this time.^{11,85}

Magnetic resonance imaging (MRI) has been reported to show an increase in cerebral white matter abnormalities in patients with CFS.^{11,84,99} Similarly, in many studies, single photon emission computed tomography (SPECT) has demonstrated changes in perfusion in certain areas of the brain in patients with CFS.^{27,38,100} In other studies, however, abnormalities specific to CFS have not been observed consistently, and methodological concerns have been raised regarding the interpretation of abnormal findings cited previously.^{25,47} An abnormality at the base of the fourth ventricle detected on focal computed tomography (CT) of the base of the brain and responding to neurosurgical intervention was reported in a group of patients with CFS,⁴⁴ but this defect is not seen on routine CT or MRI and requires confirmation by other researchers before determining its significance for these patients. At present, imaging of the central nervous system is not indicated routinely in the evaluation of a patient with CFS.

Endocrinologic Factors

Subtle defects in the hypothalamic-pituitary-adrenal axis have been described in cohorts of patients with CFS. These abnormalities include decreased free urinary cortisol levels and exaggerated adrenal

responsiveness to corticotropin infusion.³³ These changes are quantitatively minor, and mean values are still within normal for age and sex, thus rendering these values unreliable as a diagnostic test for CFS. Similar changes have been described in patients with fibromyalgia and posttraumatic stress disorder.

Cardiovascular Factors

In 1995, investigators at Johns Hopkins Hospital in Baltimore described a cohort of seven adolescents with chronic fatigue and autonomic dysfunction as assessed by tilt-table testing.⁹⁸ Furthermore these patients reported improvement or resolution of symptoms, including fatigue, with treatment of their orthostatic intolerance. Further studies from this group demonstrated some component of orthostatic hypotension in 92% of patients with CFS.⁹ Studies in groups of adults, in contrast, showed tilt-table test abnormalities in only 25% to 40% of patients.^{40,105} Whether this finding reflects true age-related differences in this phenomenon in patients with CFS is uncertain, given potential methodological differences in the performance of the tests.

The pattern of orthostatic intolerance among adolescents with CFS was characterized further by Stewart and colleagues and is consistent with the postural orthostatic tachycardia syndrome (POTS).^{111–113} Symptoms of POTS may develop after an acute infectious illness or with severe deconditioning and include fatigue, lightheadedness, impaired cognition, inappropriate sweating, headache, palpitations, nausea, vomiting, and tremulousness. These authors suggest that CFS may be an extreme expression of POTS in at least some cases.

The importance of these cardiovascular findings in CFS remains unsettled. Subjective components may contribute to defining a tilt-table test as abnormal because these studies are not performed blinded. Some healthy individuals also may experience hypotension during these tests. Further studies defining the effect of treatment of POTS on the course of CFS should help to answer this question. In this context, evaluation of, and therapy for, orthostatic changes, especially if dizziness is a significant component of the patient's complaints, may be indicated.¹³⁷

Sleep Physiology

Sleep disturbances have been described in selected groups of patients with CFS, and some of these conditions may be amenable to therapy.^{68,93} However no single pattern of sleep abnormality has been reported for these patients, and, in our experience, the pattern of hypersomnia or insomnia tends to improve as the patient recovers.¹²⁵

Psychological Factors

Psychological factors have been considered in the origin and perpetuation of CFS. Adults with CFS have demonstrated a higher frequency of depression and other psychiatric disorders before the onset of their CFS compared with age-matched controls.^{1,67} Certainly many of the symptoms reported in CFS also are reported commonly in depression. They may include sleep disturbances, loss of energy, difficulty in concentrating, changes in appetite, and musculoskeletal complaints. Studies in children and adolescents with CFS also have shown significant psychological features, especially depression and somatization, compared with both healthy controls and those with other chronic illnesses (e.g., juvenile idiopathic arthritis, cancer, cystic fibrosis).^{17,18,55,87,132} Still, certain features of CFS argue against its being solely a variant of depression. Individuals with CFS do not have the mood-related symptoms reported in patients with clinical depression. These mood-related symptoms include negative affect, anhedonia, low self-esteem, and suicidal ideation. Furthermore patients with CFS and their families have a firm belief that an infectious, immunologic, or other medical cause for their symptoms exists, and the patients desire a return to normal activities.

In considering the possible link between depression or psychological stress and CFS, several possible relationships may exist. Preexisting depression or stress may create a psychological vulnerability that allows for the development of CFS in combination with any of numerous other factors discussed previously. Studies have demonstrated a role for psychological factors predicting the response to mononucleosis and influenza.^{52,57} Similar factors may be involved in the development of CFS. Alternatively depression may be a physiologic consequence of the central nervous system changes that occur in those who develop CFS,

just as decreased concentration and memory occur as part of the syndrome.^{55,132} Furthermore reactive depression may occur in these patients in response to the inability to participate in their usual activities and to absence from school and separation from friends. Finally CFS may be, at least in some cases, a manifestation of separation anxiety or school phobia in which secondary gain, as a conversion reaction, is playing a major role. Certainly, at least a subset of adolescents and children with CFS in our experience does not appear eager to return to school or activities, and secondary gain may play a role in the perpetuation of their illness.³²

Coplan and colleagues recently described a group of patients with an anxiety disorder and a number of somatic comorbidities including joint laxity, pain syndromes (e.g., irritable bowel syndrome, fibromyalgia, chronic headaches), autoimmune and allergic disorders (e.g., hypothyroidism, asthma, allergic rhinitis with pharyngitis), and mood disorders (e.g., bipolar, major depression) that they termed anxiety-laxity-pain-immune-mood (ALPIM) syndrome.²⁶ These features share many similarities with CFS and emphasize the potential overlap of psychiatric and somatic complaints in such individuals.

In summary, each of these potential links among depression, anxiety, or stress and CFS likely plays a role, with the relative contribution of each feature varying for different people. This suggestion is consistent with the overall hypothesis that many different factors appear to contribute to the development and perpetuation of CFS. The relative contribution of these different features may vary from individual to individual and even for the same patient over the course of the illness. The assessment and management of the patient with CFS should attempt to consider these issues and their relative importance for that individual.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of CFS is one of exclusion and requires a comprehensive history. In the pediatric population, this information is obtained best from the patient and parents. Additionally we request that families bring prior medical records, test results, and pertinent school records to facilitate a complete evaluation. This process may be lengthy because the details are complicated, of long standing, and often a source of debate between the patient and parents. The history should focus on the onset of illness, the duration and severity of symptoms, prior evaluations (often multiple) as well as medical history before the illness, family history, academic performance, and social history. The physical examination of the individual with suspected CFS almost always is essentially normal despite the multitude of symptoms. Findings of mild pharyngeal erythema and cervical adenopathy commonly are reported. However finding fever, weight loss, significant adenopathy, or organomegaly should alert the clinician to the possibility of an alternative diagnosis.

DeMeirleir and colleagues reported increased detection of a 37-kDa, 2-5A-synthetase binding protein in peripheral blood mononuclear cells from patients with CFS compared with healthy controls.³² These binding proteins are related to the ribonuclease L antiviral pathway of these cells. This finding requires further confirmation before it can be considered a potential diagnostic test for CFS. At present, no specific tests for diagnosing CFS exist, and laboratory testing is aimed primarily at eliminating other possible diagnoses. Most patients have undergone multiple laboratory tests before a diagnosis of CFS has been considered, but these tests may be repeated or completed as part of the initial CFS evaluation. Additionally, interpreting previously performed tests may be part of the initial patient assessment. Screening studies may include a complete blood cell count with differential and platelets, erythrocyte sedimentation rate, hepatic and renal function studies, urinalysis, and thyroid function tests. Additional tests that may be indicated based on history and physical examination may include toxicology screening, human immunodeficiency virus serology, antinuclear antibody, rheumatoid factor, tuberculin skin test, and cortisol level. Serologic evaluations for EBV, Lyme disease, and group A streptococcal infection may be requested based on history and physical infection. In most instances, these tests are not indicated; however they often are obtained before CFS is suspected, and they need to be appropriately reviewed or repeated as part of the initial evaluation for CFS. Screening radiographic studies

may include a chest radiograph or imaging of the paranasal sinuses based on the patient's symptoms.

Elimination of every possible disorder that may cause a patient to experience prolonged fatigue is impossible, but, when guided by history, physical examination, and laboratory screening tests as outlined previously, the clinician can make a reliable diagnosis of CFS. Follow-up for periods of 4 to 13 years for pediatric patients diagnosed with CFS have not identified cases of missed or alternative diagnoses for their complaints.^{7,66} In general, the longer the duration and the greater the number of symptoms, the less the need for extensive laboratory evaluations to suggest the diagnosis of CFS. Conversely alternative diagnoses should be considered if a single symptom dominates the clinical presentation or if physical examination or laboratory tests reveal significant abnormalities.

Psychosocial assessment is indicated for all children and adolescents presenting for CFS evaluation. The extent of such evaluation may be limited to assessment by primary care personnel or may include collaboration with a social worker, psychologist, or psychiatrist based on the individual's needs and the comfort level of the examiner. Cardiorespiratory and neurologic evaluations may be used in some cases, both to consider possible alternative diagnoses and to assist in assessing factors that may be contributing to the symptoms of CFS.

MANAGEMENT

One of the essential qualities of the clinician is interest in humanity, for the secret of care of the patient is in caring for the patient.

Dr. Francis Peabody, 1926

Management of patients with CFS is aimed at providing a combination of supportive treatment and emotional support (Box 78.2).⁴¹ This process can be initiated during the initial evaluation, with a discussion of the diagnostic criteria for CFS and a review of the results of previously obtained laboratory tests. The relationship between physical and psychological symptoms can be explained, and the patient and family can be reassured that symptoms are real, even if the symptoms have psychiatric components. Additionally the patient and family can be advised that most children and adolescents with CFS do well over time^{7,36,65,66} and have a better long-term outlook than that described for adults with CFS.^{56,136} Furthermore emphasizing the frequent ups and downs in symptoms that generally characterize the course of CFS is important in assisting the patient and family to develop coping skills. This assistance

BOX 78.2 Approach to Management of Chronic Fatigue Syndrome in Children and Adolescents

- Evaluation and explanation of the diagnosis, including overview of multifactorial components
- Reassurance that symptoms are real
- Anticipatory guidance regarding secondary problems, up-and-down course of syndrome, secondary gain
- Coping skills: lifestyle modification, decreased stress, and realistic expectations and schedule
- Cognitive behavioral approaches: gradual increases in activity, an exercise program, attention to sleep patterns, attention to nutrition
- Psychological support for individual and family
- Educational issues: return to classes, home tutors, neuropsychiatric testing as indicated
- Relationship issues: friends and family
- Follow-up plan: monitoring of physical symptoms and psychological issues, ongoing guidance and reassurance (follow-up visits every 4–6 weeks)
- Minimize shopping for a doctor, unnecessary testing, family strain, and unconventional, unproven, or experimental therapies

Modified from Krilov LR, Fisher M. Chronic fatigue syndrome in children and adolescents. *Contemp Pediatr*. 2002;19:61–8.

may include guidance on how to modify lifestyle most appropriately and how to set realistic schedules and goals. Studies from the United Kingdom suggest that formal cognitive behavioral therapy^{30,92,102,135} or graded exercise programs, or both, may be beneficial for patients with CFS.^{20,43,70,131,134}

Consistent with this approach, results from a series of interviews with children diagnosed with CFS reported by Parslow and colleagues suggest that supportive schools, families, and friends as well as development of coping skills to manage activities could help ameliorate symptoms.⁸⁶

Although, as noted earlier, the prognosis for children and adolescents with CFS is generally favorable, Roberts and colleagues suggest a possible increase in rate of suicide in 2147 cases of CFS followed at a CFS referral center over a 7-year period.⁹⁷

Many other therapies have been advocated by different groups for patients with CFS. These treatments may include supplements, such as essential fatty acids,¹³⁰ magnesium,²⁸ liver extract injections,⁵⁸ and vitamin and nutritional supplements,⁷⁸ as well as pharmacologic treatments, such as corticosteroids,^{22,81,88} reduced nicotinamide adenine dinucleotide,¹²⁸ antidepressants,^{83,127} and growth hormone.⁸² A recent brief observation report suggested that methylphenidate may be beneficial in relieving fatigue and improving concentration in some patients with CFS.⁸ Homeopathic therapies, osteopathy, and massage therapy³⁷ also have been reported to be beneficial in the management of CFS. Most of these approaches have not been studied adequately to allow definitive comment on their potential benefit for a given patient. Still, the clinician should be aware of them to help guide patients who are likely to hear about them from other patients or outside sources, including the Internet.^{44,133,135}

PROGNOSIS AND FUTURE DIRECTIONS

CFS likely affects heterogeneous groups of patients, and a single cause or definitive treatment modality most likely will not be uncovered. Nonetheless studying groups of such patients yields helpful information

on the pathophysiology of this condition, and useful steps to address and alleviate symptoms for patients have been reported. In recognition of the significance of this entity, the CDC launched an awareness campaign, including the development of an Internet site for health care professionals and the public (<http://www.cdc.gov/cfs/>). In addition, long-term follow-up data demonstrating improvement over the course of time, especially in children and adolescents, without emergence of significant other conditions, are encouraging for patients, families, and clinicians caring for such individuals.

Nomenclature for Aerobic and Anaerobic Bacteria

David A. Bruckner

Table 79.1 represents an update of the current nomenclature, taxonomy, and classification of various microbial agents and is based on the organism's phenotypic and genotypic characteristics. Organisms included in this chapter are those that have been associated with pathologic processes or are medically significant. The current names are either officially recognized or proposed for recognition and currently used in the literature. Some organisms have been characterized but have never been cultured.

Taxonomic ranks for naming bacterial organisms include kingdom, division, class, order, family, genus, species, and subspecies. All of these ranks have official standing in nomenclature. Each taxonomic name should be represented by a nomenclature type. The species is represented by a type strain that is deposited in recognized culture collections.³ Nomenclature priorities for bacteriologic names date back to May 1753. Because of difficulties in searching the literature and limited available information on described species, approved lists of bacterial names were published in the *International Journal of Systematic Bacteriology* in 1980. Names not included on those lists have lost all standing in nomenclature status.

Bacterial classification had relied on phenotypic information using physical characteristics and biochemical reactions; however these were

poor parameters for establishing genetic relatedness. Multivariate analysis has played a large role in classification since the 1950s. DNA hybridization, rRNA-DNA hybridization, gene sequence analysis, and multilocus sequence analysis have played a major role in determining classifications. A prime example of this is reclassification of some species from the genus *Pseudomonas* to *Burkholderia* to *Ralstonia* (*R. pickettii*) or *Pseudomonas maltophilia* to *Xanthomonas maltophilia* to *Stenotrophomonas maltophilia*. Some changes are necessary due to a lack of criteria to define a genus or classification that was based on a single or limited number of isolates.

The *International Code of Nomenclature of Bacteria*⁵ includes rules on how to name bacteria and use the name. Comprehensive taxonomic information for bacteriologic classification is found in *Bergey's Manual of Systematic Bacteriology*,^{1,2,4,6,7} volumes 1 through 5. Names are validated only when they are included in the validation lists regularly published by the *International Journal of Systematic and Evolutionary Microbiology*.^{3,5} An overview of validly published names can be viewed at <http://www.bacterio.cict.fr> or <http://www.dsmz.de/bacterial-diversity/prokaryotic-nomenclature-up-to-date>.

TABLE 79.1 Current Bacterial Nomenclature, Taxonomy, and Classification

Current Name	Synonym	Current Name	Synonym
I. Aerobic Gram-Positive Cocci		<i>Staphylococcus saprophyticus</i> subspecies <i>bovis</i>	<i>Micrococcus</i> subgroup 3
Characteristics: Aerotolerant anaerobes that can occur singly or in pairs, tetrads, chains, or clusters; they can be catalase positive or catalase negative. Organisms positive for coagulase or clumping factor include <i>Staphylococcus aureus</i> , <i>Staphylococcus intermedius</i> , <i>Staphylococcus lugdunensis</i> , and <i>Staphylococcus schleiferi</i> subspecies <i>coagulans</i>		<i>Staphylococcus saprophyticus</i> subspecies <i>saprophyticus</i>	<i>Staphylococcus saprophyticus</i> subspecies <i>saprophyticus</i>
Catalase-Positive Organisms		<i>Staphylococcus schleiferi</i> subspecies <i>coagulans</i>	
<i>Alloiococcus otitidis</i>	<i>Alloiococcus otitis</i>	<i>Staphylococcus schleiferi</i> subspecies <i>schleiferi</i>	
<i>Auritidibacter ignavus</i>		<i>Staphylococcus sciuri</i> subspecies <i>camaticus</i>	
<i>Dermacoccus nishinomiyaensis</i>		<i>Staphylococcus sciuri</i> subspecies <i>rodentium</i>	
<i>Kocuria carniphila</i>		<i>Staphylococcus sciuri</i> subspecies <i>sciuri</i>	
<i>Kocuria kristinae</i>	<i>Micrococcus kristinae</i>	<i>Staphylococcus simiae</i>	
<i>Kocuria rhizophila</i>		<i>Staphylococcus simulans</i>	
<i>Kocuria rosea</i>	<i>Micrococcus roseus</i>	<i>Staphylococcus succinus</i> subspecies <i>casei</i>	
<i>Kocuria varians</i>	<i>Micrococcus varians</i>	<i>Staphylococcus succinus</i> subspecies <i>succinus</i>	
<i>Kytococcus schroeteri</i>		<i>Staphylococcus warneri</i>	
<i>Kytococcus sedentarius</i>	<i>Micrococcus sedentarius</i>	<i>Staphylococcus xylosus</i>	
<i>Micrococcus luteus</i>		Catalase-Negative Organisms	
<i>Micrococcus lylae</i>		<i>Abiotrophia defectiva</i>	<i>Streptococcus defectivus</i> Nutritionally variant streptococci
<i>Rothia mucilaginosa</i>		<i>Aerococcus christensenii</i>	
<i>Staphylococcus arlettae</i>		<i>Aerococcus sanguinicola</i>	<i>Aerococcus sanguicola</i>
<i>Staphylococcus aureus</i> subspecies <i>anaerobius</i>		<i>Aerococcus urinae</i>	
<i>Staphylococcus aureus</i> subspecies <i>aureus</i>		<i>Aerococcus urinaehominis</i>	
<i>Staphylococcus auricularis</i>		<i>Aerococcus viridans</i>	
<i>Staphylococcus capitis</i> subspecies <i>capitis</i>		<i>Dolosicoccus paucivorans</i>	
<i>Staphylococcus capitis</i> subspecies <i>ureolyticus</i>		<i>Dolosigranulum pigrum</i>	
<i>Staphylococcus caprae</i>		<i>Enterococcus avium</i>	<i>Streptococcus avium</i> Group D <i>Enterococcus</i>
<i>Staphylococcus carnosus</i> subspecies <i>carnosus</i>		<i>Enterococcus caccae</i>	
<i>Staphylococcus carnosus</i> subspecies <i>utilis</i>		<i>Enterococcus casseliflavus</i>	<i>Enterococcus flavescens</i> <i>Streptococcus casseliflavus</i>
<i>Staphylococcus cohnii</i> subspecies <i>cohnii</i>		<i>Enterococcus cecorum</i>	<i>Streptococcus cecorum</i>
<i>Staphylococcus cohnii</i> subspecies <i>urealyticus</i>		<i>Enterococcus dispar</i>	
<i>Staphylococcus condimenti</i>		<i>Enterococcus durans</i>	<i>Streptococcus durans</i> Group D <i>Enterococcus</i>
<i>Staphylococcus epidermidis</i>	<i>Staphylococcus albus</i>	<i>Enterococcus faecalis</i>	<i>Streptococcus faecalis</i> Group D <i>Enterococcus</i>
<i>Staphylococcus felis</i>		<i>Enterococcus faecium</i>	<i>Streptococcus faecium</i> Group D <i>Enterococcus</i>
<i>Staphylococcus gallinarum</i>		<i>Enterococcus gallinarum</i>	<i>Streptococcus gallinarum</i>
<i>Staphylococcus haemolyticus</i>		<i>Enterococcus gilvus</i>	
<i>Staphylococcus hominis</i> subspecies <i>hominis</i>		<i>Enterococcus hawaiiensis</i>	
<i>Staphylococcus hominis</i> subspecies <i>novobioceticus</i>		<i>Enterococcus hirae</i>	
<i>Staphylococcus hyicus</i>		<i>Enterococcus italicus</i>	<i>Enterococcus saccharominimus</i>
<i>Staphylococcus intermedius</i>		<i>Enterococcus malodoratus</i>	
<i>Staphylococcus kloosii</i>		<i>Enterococcus mundtii</i>	
<i>Staphylococcus lentus</i>	<i>Staphylococcus sciuri</i> subspecies <i>lentus</i>	<i>Enterococcus pallens</i>	
<i>Staphylococcus lugdunensis</i>		<i>Enterococcus pseudoavium</i>	
<i>Staphylococcus massiliensis</i>		<i>Enterococcus raffinosus</i>	
<i>Staphylococcus nepalensis</i>		<i>Enterococcus sanguinicola</i>	
<i>Staphylococcus pasteurii</i>		<i>Enterococcus thailandicus</i>	
<i>Staphylococcus pettenkoferi</i>		<i>Facklamia hominis</i>	
<i>Staphylococcus pseudintermedius</i>		<i>Facklamia ignava</i>	
<i>Staphylococcus saccharolyticus</i>	<i>Peptococcus saccharolyticus</i>	<i>Facklamia languida</i>

Current Name	Synonym	Current Name	Synonym
<i>Facklamia sourekkii</i>		<i>Streptococcus mutans</i> group	<i>Viridans streptococci</i>
<i>Gemella bergeri</i>	<i>Gemella bergeriae</i>	<i>Streptococcus criceti</i>	
<i>Gemella haemolysans</i>	<i>Neisseria haemolysans</i>	<i>Streptococcus downei</i>	
<i>Gemella morbillorum</i>	<i>Streptococcus morbillorum</i>	<i>Streptococcus mutans</i>	
	<i>Peptostreptococcus morbillorum</i>	<i>Streptococcus rattii</i>	
		<i>Streptococcus sobrinus</i>	
<i>Gemella sanguinis</i>		<i>Streptococcus pyogenes</i> group	
<i>Globicatella sanguinis</i>	Salt-tolerant viridans streptococci	<i>Streptococcus agalactiae</i>	
<i>Granulicatella adiacens</i>	<i>Abiotrophia adiacens</i>	<i>Streptococcus canis</i>	
	<i>Streptococcus adiacens</i>	<i>Streptococcus dysgalactiae</i>	
	Nutritionally variant streptococci	subspecies <i>equisimilis</i>	
<i>Granulicatella elegans</i>	<i>Abiotrophia elegans</i>	<i>Streptococcus equi</i> subspecies	
	Nutritionally variant streptococci	<i>zooepidermidis</i>	
<i>Granulicatella para-adiacens</i>		<i>Streptococcus iniae</i>	
<i>Helcococcus kunzii</i>		<i>Streptococcus porcinus</i>	
<i>Helcococcus sueciensis</i>		<i>Streptococcus pyogenes</i>	
<i>Ignavigranum ruoffiae</i>		<i>Streptococcus salivarius</i> group	Viridans streptococci
<i>Lactococcus garvieae</i>	<i>Streptococcus garvieae</i>	<i>Streptococcus salivarius</i>	
	Lancefield group N	<i>Streptococcus thermophiles</i>	
<i>Lactococcus lactis</i>		<i>Streptococcus vestibularis</i>	
<i>Leuconostoc citreum</i>		<i>Streptococcus suis</i>	
<i>Leuconostoc lactis</i>		<i>Tetragenococcus halophilus</i>	<i>Pediococcus halophilus</i>
<i>Leuconostoc mesenteroides</i>		<i>Tetragenococcus solitarius</i>	<i>Enterococcus solitarius</i>
<i>Leuconostoc pseudomesenteroides</i>		<i>Vagococcus fluvialis</i>	
<i>Pediococcus acidilactici</i>		<i>Weissella paramesenteroides</i>	<i>Leuconostoc paramesenteroides</i>
<i>Pediococcus pentosaceus</i>		II. Anaerobic Gram-Positive Cocci	
<i>Streptococcus acidominimus</i>		Characteristics: Occur singly or in pairs, chains, or clumps	
<i>Streptococcus anginosus</i> group	Viridans streptococci	<i>Anaerococcus hydrogenalis</i>	<i>Peptostreptococcus hydrogenalis</i>
<i>Streptococcus anginosus</i>		<i>Anaerococcus lactolyticus</i>	<i>Peptostreptococcus lactolyticus</i>
<i>Streptococcus constellatus</i>		<i>Anaerococcus murchisonii</i>	
subspecies <i>constellatus</i>		<i>Anaerococcus octavius</i>	<i>Peptostreptococcus octavius</i>
<i>Streptococcus constellatus</i>		<i>Anaerococcus prevotii</i>	<i>Peptostreptococcus prevotii</i>
subspecies <i>pharyngis</i>		<i>Anaerococcus tetradius</i>	<i>Peptostreptococcus tetradius</i>
<i>Streptococcus constellatus</i>		<i>Anaerococcus vaginalis</i>	
subspecies <i>viborgensis</i>		<i>Anaerosphaera aminiphila</i>	
<i>Streptococcus intermedius</i>		<i>Atopobium parvulum</i>	
<i>Streptococcus bovis</i> group	Group D streptococci	<i>Blautia coccoides</i>	<i>Clostridium coccoides</i>
<i>Streptococcus alactolyticus</i>		<i>Blautia productus</i>	<i>Peptostreptococcus productus</i>
<i>Streptococcus bovis</i>			<i>Ruminococcus productus</i>
<i>Streptococcus equinus</i>		<i>Blautia wexlerae</i>	
<i>Streptococcus gallolyticus</i>		<i>Fingoldia magna</i>	<i>Peptococcus magnus</i>
subspecies <i>gallolyticus</i>		<i>Murdochella asaccharolytica</i>	
<i>Streptococcus gallolyticus</i>		<i>Parvimonas micra</i>	<i>Peptostreptococcus micros</i>
subspecies <i>macedonicus</i>			<i>Micromonas micros</i>
<i>Streptococcus gallolyticus</i>		<i>Peptococcus niger</i>	<i>Micrococcus niger</i>
subspecies <i>pasteurianus</i>		<i>Peptoniphilus asaccharolyticus</i>	<i>Peptostreptococcus asaccharolyticus</i>
<i>Streptococcus infantarius</i>		<i>Peptoniphilus coxii</i>	
subspecies <i>coli</i>		<i>Peptoniphilus duerdenii</i>	
<i>Streptococcus infantarius</i>		<i>Peptoniphilus gorbachii</i>	
subspecies <i>infantarius</i>		<i>Peptoniphilus harei</i>	<i>Peptostreptococcus harei</i>
<i>Streptococcus hongkongensis</i>		<i>Peptoniphilus indolicus</i>	
<i>Streptococcus mitis</i> group	Viridans streptococci	<i>Peptoniphilus ivorii</i>	<i>Peptostreptococcus ivorii</i>
<i>Streptococcus australis</i>		<i>Peptoniphilus koeoneniae</i>	
<i>Streptococcus cristatus</i>		<i>Peptoniphilus lacrimalis</i>	<i>Peptostreptococcus lacrimalis</i>
<i>Streptococcus gordonii</i>		<i>Peptoniphilus olseni</i>	
<i>Streptococcus infantis</i>		<i>Peptostreptococcus anaerobius</i>	
<i>Streptococcus massiliensis</i>		<i>Peptostreptococcus indolicus</i>	<i>Peptococcus indolicus</i>
<i>Streptococcus mitis</i>		<i>Peptostreptococcus magna</i>	<i>Peptococcus magnus</i>
<i>Streptococcus oralis</i>			<i>Peptococcus variabilis</i>
<i>Streptococcus oligofermentans</i>		<i>Peptostreptococcus massiliae</i>	
<i>Streptococcus orisratti</i>		<i>Peptostreptococcus stomatis</i>	
<i>Streptococcus parasanguinis</i>		<i>Peptostreptococcus trisimilis</i>	
<i>Streptococcus peroris</i>		<i>Ruminococcus gauvreauii</i>	<i>Streptococcus hansenii</i>
<i>Streptococcus pneumoniae</i>		<i>Slackia heliotrinireducens</i> corrig	<i>Peptostreptococcus heliotrinireducens</i>
<i>Streptococcus pseudopneumoniae</i>			
<i>Streptococcus sanguinis</i>			
<i>Streptococcus sinensis</i>

Current Name	Synonym	Current Name	Synonym
III. Aerobic Gram-Negative Cocci		<i>Arthrobacter oxydans</i>	
Characteristics: Occur singly or in pairs or clumps; catalase and oxidase positive		<i>Bacillus anthracis</i>	
<i>Lautropia mirabilis</i>	<i>Sarcina mirabilis</i>	<i>Bacillus cereus</i>	
<i>Neisseria bacilliformis</i>		<i>Bacillus circulans</i>	
<i>Neisseria canis</i>		<i>Bacillus coagulans</i>	
<i>Neisseria cinerea</i>	<i>Micrococcus cinereus</i>	<i>Bacillus cytotoxicus</i>	
	<i>Neisseria pharyngis</i>	<i>Bacillus firmus</i>	
<i>Neisseria elongata</i> subspecies <i>elongata</i>	<i>Neisseria elongata</i>	<i>Bacillus idriensis</i>	
<i>Neisseria elongata</i> subspecies <i>glycolytica</i>	<i>Neisseria elongata</i>	<i>Bacillus infantis</i>	
<i>Neisseria elongata</i> subspecies <i>nitroreducens</i>	<i>Neisseria elongate</i> CDC group M-6	<i>Bacillus lentus</i>	
<i>Neisseria flavescens</i>		<i>Bacillus licheniformis</i>	
<i>Neisseria gonorrhoeae</i>		<i>Bacillus megaterium</i>	
<i>Neisseria lactamica</i>	<i>Neisseria lactamicus</i>	<i>Bacillus mycoides</i>	
<i>Neisseria meningitidis</i>		<i>Bacillus pumilus</i>	
<i>Neisseria mucosa</i>		<i>Bacillus sphaericus</i>	
<i>Neisseria polysaccharea</i>		<i>Bacillus subtilis</i>	
<i>Neisseria shayegani</i>		<i>Bacillus thuringiensis</i>	
<i>Neisseria sicca</i>		<i>Brevibacillus agri</i>	<i>Bacillus agri</i>
<i>Neisseria subflava</i> biovar <i>flava</i>	<i>Neisseria subflava</i>	<i>Brevibacillus brevis</i>	<i>Bacillus brevis</i>
<i>Neisseria subflava</i> biovar <i>perflava</i>	<i>Neisseria subflava</i>	<i>Brevibacillus centrosporus</i>	
<i>Neisseria subflava</i> biovar <i>subflava</i>	<i>Neisseria subflava</i>	<i>Brevibacillus laterosporus</i>	<i>Bacillus laterosporus</i>
<i>Neisseria wadsworthii</i>		<i>Brevibacillus parabrevis</i>	CDC coryneform groups B-1 and B-3
<i>Neisseria weaveri</i>	<i>Moraxella</i> sp. M-5 CDC group M-5	<i>Brevibacterium casei</i>	
IV. Anaerobic Gram-Negative Cocci		<i>Brevibacterium luteolum</i>	
Characteristics: Occur in pairs or clumps		<i>Brevibacterium mcbrellneri</i>	
<i>Acidaminococcus fermentans</i>		<i>Brevibacterium sanguinis</i>	
<i>Acidaminococcus intestini</i>		<i>Cellulomonas denverensis</i>	CDC coryneform group A-3
<i>Anaeroglobus geminatus</i>		<i>Cellulomonas hominis</i>	
<i>Megasphaera elsdenii</i>	<i>Peptostreptococcus elsdenii</i>	<i>Cellulosimicrobium cellulans</i>	<i>Cellulomonas cellulans</i> <i>Oerskovia xanthineolytica</i> CDC coryneform groups A-1 and A-2
<i>Megasphaera micronuciformis</i>		<i>Cellulosimicrobium funkei</i>	
<i>Negativicoccus</i> spp.		<i>Corynebacterium accolens</i>	
<i>Veillonella alcalescens</i>		<i>Corynebacterium afermentans</i> subspecies <i>afermentans</i>	CDC coryneform group ANF-1
<i>Veillonella atypica</i>		<i>Corynebacterium afermentans</i> subspecies <i>lipophilum</i>	CDC coryneform group ANF-1
<i>Veillonella denticariosi</i>		<i>Corynebacterium amycolatum</i>	<i>Corynebacterium xerosis</i> <i>Corynebacterium minutissimum</i> <i>Corynebacterium striatum</i> CDC coryneform groups F-2 and I-2
<i>Veillonella dispar</i>		<i>Corynebacterium aquaticum</i>	
<i>Veillonella montpellierensis</i>		<i>Corynebacterium appendicis</i>	
<i>Veillonella parvula</i>		<i>Corynebacterium argenteoratense</i>	
V. Aerobic Gram-Positive Bacilli		<i>Corynebacterium atypicum</i>	
Characteristics: Rodlike; catalase negative or catalase positive; some are acid-fast stain-positive, and some have branching. Only <i>Bacillus</i> , <i>Brevibacillus</i> , and <i>Brevibacterium</i> spp. produce spores		<i>Corynebacterium aurimucosum</i>	CDC fermentative coryneform group 4
<i>Actinomadura chibensis</i>		<i>Corynebacterium auris</i>	<i>Corynebacterium nigricans</i> CDC coryneform group ANF-1
<i>Actinomadura crenea</i>		<i>Corynebacterium bovis</i>	
<i>Actinomadura dassonvillei</i>		<i>Corynebacterium canis</i>	
<i>Actinomadura latina</i>		<i>Corynebacterium confusum</i>	
<i>Actinomadura madurae</i>		<i>Corynebacterium coyleae</i>	
<i>Actinomadura nitritigenes</i>		<i>Corynebacterium diphtheriae</i>	
<i>Actinomadura pelletieri</i>		<i>Corynebacterium durum</i>	
<i>Actinomadura spuuti</i>		<i>Corynebacterium falsenii</i>	
<i>Arcanobacterium bernardiae</i>	<i>Actinomyces bernardiae</i> CDC coryneform group 2	<i>Corynebacterium freiburgense</i>	
<i>Arcanobacterium haemolyticum</i>	<i>Corynebacterium haemolyticum</i>	<i>Corynebacterium freneyi</i>	
<i>Arcanobacterium pyogenes</i>	<i>Actinomyces pyogenes</i> <i>Corynebacterium pyogenes</i>	<i>Corynebacterium glucuronolyticum</i>	
<i>Arthrobacter albus</i>		<i>Corynebacterium hansenii</i>	
<i>Arthrobacter cummingsii</i>		<i>Corynebacterium imitans</i>

TABLE 79.1 Current Bacterial Nomenclature, Taxonomy, and Classification—cont'd

Current Name	Synonym	Current Name	Synonym
<i>Scardovia inopinata</i>	<i>Bifidobacterium inopinatum</i> <i>Bifidobacterium dentium</i>	<i>Clostridium tertium</i>	
<i>Scardovia wiggsiae</i>		<i>Clostridium tetani</i>	
<i>Shuttleworthia satellites</i>		<i>Filifactor alocis</i>	<i>Fusobacterium alocis</i>
<i>Slackia exigua</i>	<i>Eubacterium exiguum</i>	<i>Filifactor villosus</i>	<i>Clostridium villosum</i>
<i>Slackia heliotrinireducens</i>		<i>Tissierella praeacuta</i>	<i>Bacteroides praeacutus</i> <i>Clostridium hastiforme</i>
<i>Solobacterium moorei</i>		VIII. Aerobic Gram-Negative Bacilli: Enterobacteriaceae	
<i>Varibaculum cambriense</i>		Characteristics: Ferment sugars; are oxidase-negative; most reduce nitrate to nitrite. Diagnostic laboratories may report <i>Salmonella</i> serovars by name (e.g., <i>Salmonella typhi</i> or <i>Salmonella</i> serovar <i>Typhi</i>)	
VII. Anaerobic Gram-Positive Bacilli (Spore-Forming)		<i>Buttiauxella gaviniae</i>	
Characteristics: Broad, short bacilli with blunt ends. Most organisms readily produce spores, except <i>Clostridium perfringens</i> and <i>Tissierella praeacuta</i>		<i>Buttiauxella noackiae</i>	CDC enteric group 59
<i>Clostridium argentinense</i>	<i>Clostridium botulinum</i> group G <i>Clostridium subterminale</i> <i>Clostridium hastiforme</i>	<i>Cedecea davisae</i>	CDC enteric group 15
<i>Clostridium baratii</i>	<i>Clostridium barati</i> <i>Clostridium parapertingens</i> <i>Clostridium perenne</i>	<i>Cedecea lapagei</i>	
<i>Clostridium bifermentans</i>		<i>Cedecea neteri</i>	
<i>Clostridium bolteae</i>		<i>Citrobacter amalonaticus</i>	<i>Levinea amalonatica</i>
<i>Clostridium botulinum</i>	<i>Clostridium putrificum</i>	<i>Citrobacter braakii</i>	<i>Citrobacter freundii</i>
<i>Clostridium butyricum</i>	<i>Clostridium pseudotetanicum</i>	<i>Citrobacter farmeri</i>	<i>Citrobacter amalonaticus</i> biogroup 1
<i>Clostridium cadaveris</i>		<i>Citrobacter freundii</i>	<i>Colobactrum freundii</i>
<i>Clostridium carnis</i>		<i>Citrobacter gillenii</i>	<i>Citrobacter genomospecies</i> 10 <i>Citrobacter freundii</i>
<i>Clostridium celerecrescens</i>		<i>Citrobacter koseri</i>	<i>Citrobacter diversus</i> <i>Levinea malonatica</i>
<i>Clostridium chauvoei</i>		<i>Citrobacter murlinae</i>	<i>Citrobacter genomospecies</i> 11 <i>Citrobacter freundii</i>
<i>Clostridium clostridioforme</i>	<i>Clostridium clostridioforme</i>	<i>Citrobacter rodentium</i>	<i>Citrobacter genomospecies</i> 9 <i>Citrobacter freundii</i>
<i>Clostridium coccides</i>		<i>Citrobacter sedlakii</i>	<i>Citrobacter genomospecies</i> 8 <i>Citrobacter freundii</i>
<i>Clostridium cocleatum</i>		<i>Citrobacter werkmanii</i>	<i>Citrobacter genomospecies</i> 7 <i>Citrobacter freundii</i>
<i>Clostridium difficile</i>	<i>Clostridium difficile</i>	<i>Citrobacter youngae</i>	<i>Citrobacter genomospecies</i> 5 <i>Citrobacter freundii</i>
<i>Clostridium disporicum</i>		<i>Cronobacter condimenti</i>	<i>Enterobacter sakazakii</i>
<i>Clostridium fallax</i>	<i>Clostridium pseudofallax</i>	<i>Cronobacter dublinensis</i>	<i>Enterobacter sakazakii</i>
<i>Clostridium ghonii</i>	<i>Clostridium ghoni</i>	<i>Cronobacter malonaticus</i>	<i>Enterobacter sakazakii</i>

SUBSECTION I Gram-Positive Cocci

80

***Staphylococcus aureus* Infections (Coagulase-Positive Staphylococci)**

Sheldon L. Kaplan • Kristina G. Hulten • Edward O. Mason Jr

Staphylococcus aureus is a gram-positive coccus that occurs in pairs, chains, and grapelike clusters (Fig. 80.1). *S. aureus* is ubiquitous in nature and can be pathogenic for humans and animals. Staphylococci are nonmotile, are aerobic or facultative anaerobic, and are readily cultivated on routine laboratory media. These organisms are part of the normal human flora. *S. aureus* is responsible for an impressive variety of diseases ranging from minor skin and soft tissue infections to major life-threatening and fatal

infections such as bacteremia, endocarditis, pericarditis, pneumonia, empyema, osteomyelitis, myositis, and septic arthritis. The focus of this chapter is on epidemiology, virulence factors, pathogenesis, diagnosis, and treatment of infections caused by *S. aureus*. The reader is referred to the many chapters in this textbook that address the specific infections noted.

On blood agar, *S. aureus* forms round, convex, shiny opaque colonies 1 to 4 mm in diameter, often with a zone of clear β -hemolysis

(Fig. 80.2) surrounding the colony. Pigment production is variable, with strains exhibiting a yellow or golden pigment on primary isolation; yellow pigment is actually an *S. aureus* virulence factor.¹⁹⁵ *S. aureus* secretes free coagulase, and this is the basis for the most definitive and most accepted method for identification of pathogenic staphylococci associated with human and animal infection. Free coagulase reacts with coagulase activator in plasma and converts fibrinogen to fibrin with the formation of a fibrin clot. Coagulase also can be evaluated by testing for bound coagulase or clumping factor in a rapid slide test (Fig. 80.3). Clumping factor bound to the organism acts directly on fibrinogen

FIG. 80.1 Staphylococci in pus. The organisms tend to form clusters, are round, and stain purple with Gram stain (positive), similar to bunches of grapes.

FIG. 80.2 Typical hemolysis produced by *Staphylococcus aureus* on sheep blood agar.

and converts it to fibrin; it is detected by visible clumping or agglutination when a suspension is incubated with plasma. The bound coagulase test is used commonly in clinical laboratories and is more rapid than the tube coagulase test. However, the slide test for clumping factor may be falsely negative in 10% to 15% of cases. Thus a negative slide coagulase test with an isolate that is highly suggestive of being *S. aureus* should be confirmed with a tube coagulase test for free coagulase.^{178,262} A limited number of biochemical reactions can differentiate *S. aureus* from other staphylococci (Table 80.1). Commercially available molecular techniques can rapidly detect *S. aureus* from blood cultures with gram-positive cocci in clusters. By including gene targets both for an *S. aureus*-specific gene and a sequence near the insertion site of the staphylococcal cassette chromosome *mec* element (SCC*mec*) in the assay, it is possible to detect *S. aureus* and distinguish methicillin-susceptible (MSSA) isolates from methicillin-resistant (MRSA) isolates simultaneously. The rapid detection of *S. aureus* and methicillin susceptibility using these molecular tests impacts patient care by allowing more timely modification of treatment to the most appropriate antibiotic.^{100,298}

STRUCTURE

Capsule

Capsule production often is considered a virulence factor and frequently is used by bacteria to hinder phagocytosis by the host.²⁴⁰ Karakawa and colleagues described a scheme of eight *S. aureus* capsular types in 1982.¹⁶⁴ Subsequently, Sompolinsky and associates described three more serotypes, bringing the total number to 11.²⁹⁵ Most *S. aureus* organisms are encapsulated to a varying degree (Fig. 80.4). Two serotypes (1 and 2) produce mucoid colonies on agar media but are rare among clinical isolates.²⁹⁵ Serotypes 5 and 8 account for about 75% of strains recovered from infections in humans, including children.^{65,274,307} In practice, strains that do not belong to serotypes 1, 2, 5, or 8 are referred to as *nontypeable*.¹³⁶ The role of capsule polysaccharide in virulence comes primarily from studies of CP5 and CP8 and is not completely clear. These studies show that inhibition of phagocytosis by capsule can result in persistence on surfaces but modulates adherence to endothelial surfaces.²⁴⁰ A protein conjugate vaccine composed of CP5 and CP8

FIG. 80.3 Bound (slide) coagulase test. A suspension of organisms is mixed with plasma. Immediate clumping (reaction on the left) indicates both the presence of bound coagulase and the fact that the organism is coagulase positive.

FIG. 80.4 Structure of *Staphylococcus aureus*. TSST-1, toxic shock syndrome toxin type 1. (From Daum RS, Spellberg B. Progress toward a *Staphylococcus aureus* vaccine. *Clin Infect Dis*. 2012;54[4]:560–567.)

conjugated to nontoxic recombinant *Pseudomonas aeruginosa* exotoxin A (StaphVax) initially appeared promising in prevention of *S. aureus* bacteremia in hemodialysis patients.²⁸⁸ However, in a larger study this vaccine was not found to be efficacious.²⁸⁷ Combinations including capsular polysaccharides in addition to other pathogenicity or virulence factors may prove more successful.²³⁹ The major clone of MRSA associated with community-onset infections, USA300, as well as USA300 MSSA isolates and USA500 isolates do not express a capsular polysaccharide due to mutations in the *cap5* locus, casting doubt on the contribution of the capsule to virulence of the organism.^{33,307}

Protein A

Staphylococcal protein A, a major component of the cell wall of coagulase-positive staphylococci, has been found to bind to the Fc portion of immunoglobulin (Ig) G (IgG). This binding is nonimmune. It differs from specific antigen-antibody reactions in that the reaction is non-specific, although both precipitation and agglutination are observed. Protein A binds the IgG of many mammalian species. This property has rendered protein A a major reagent in many immune assays. Protein A has also been found to bind to platelets through the platelet *gC1qr*, a 33-kDa cell protein,²³⁷ as well as to von Willebrand factor,¹²⁷ both of which may be important in the pathogenesis of endovascular infections caused by *S. aureus*. Protein A plays a central role in the pathogenesis of staphylococcal pneumonia in that TNFR1, a receptor for tumor necrosis factor- α , is also receptor for protein A, and thus protein A is a principal staphylococcal proinflammatory factor in the lung.^{109,249} The complex interactions of protein A, as well as other virulence factors, and the host in the pathogenesis of *S. aureus* pneumonia was reviewed by Parker and Prince.²⁴⁹ Protein A also may play a role in modulating the duration of nasal carriage by influencing innate host defenses.⁵⁴ The gene encoding for protein A, *spa*, contains a polymorphic repeat region, which is the target for *spa* typing, a molecular method frequently used to characterize *S. aureus*.¹²⁶

Extracellular Products

S. aureus elaborates a wide variety of extracellular toxins, many of which have potent biologic effects in the isolated state on intact animals, tissues, cells, and membranes. These toxins generally are thought to be responsible

for the virulence of *S. aureus*, and the role of several of these products in staphylococcal infections has been proved definitively in humans. The important staphylococcal extracellular products include α -, β -, γ - and δ -hemolysins, coagulases, leukocidin, hyaluronidase, staphylokinase, bacteriocins, the epidermolytic toxins, toxic shock syndrome toxin type 1 (TSST-1), and the enterotoxins. In recent years a group of cytolytic peptides, the phenol-soluble modulins (PSM), have gained attention for their moderate cytolytic capacity, although the precise function of these molecules remains unclear.¹⁷² PSM contribute to biofilm formation and are produced most highly by isolates recovered from skin and soft tissue infections, supporting the hypothesis that PSM play an important role in the pathogenesis of skin and soft tissue infections.^{245,264} The pore-forming toxins include α hemolysin, γ hemolysin, Pantone-Valentine leukocidin (PVL), LukED, and LukAB (also referred to as LukGH).^{76,325}

S. aureus mobile genetic elements include pathogenicity islands, plasmids, and phages.²¹⁰ Almost half of the known toxins and virulence genes in *S. aureus* are found in pathogenicity islands. These genetic clusters, commonly of 15 to 20 kb, also contain genetic elements such as integrases and transposases. A high genetic instability is associated with many of these islands, and mosaic structures are common findings. A growing number of pathogenicity islands (vSa) have been described.^{87,103,190,191,192,210,343} Although polymorphisms in gene content occur, studies have shown genetic conservation within specific lineages of *S. aureus*. All sequenced strains of *S. aureus* contain the genomic islands vSa α , vSa β , and vSa γ .^{70,103,137,122}

Hemolysins and Leukocidins

Encoded by *hla*, α hemolysin is produced by most *S. aureus* isolates and is a classic pore-forming bacterial toxin. The purified toxin has impressive hemolytic, dermonecrotic, and lethal properties. The protein interacts with and damages a variety of cell membranes, releases hemoglobin from erythrocytes of various mammalian and avian species, and is cytotoxic to a number of cell lines in tissue culture. It lyses rabbit and human platelets and disrupts lysosomes. It causes contraction in skeletal and vascular smooth muscle, with the latter action perhaps explaining its property of causing localized dermal necrosis. In a rat model, α toxin damaged the air–blood barrier in vivo during *S. aureus*

pneumonia.²¹⁶ The α toxin forms pores in the membranes of endothelial cells, leading to vasoconstriction and increasing vascular permeability, and also has effects that lead to apoptosis of a number of different cells.⁷² Damage from the α toxin to endothelial cells is mediated via its binding to the receptor for A-disintegrin and metalloprotease 10 (ADAM10).²⁵⁶ This toxin also is an important activator of caspase 1/calpain signaling, which leads to pyroptosis, a form of inflammatory death, of human keratinocytes in vitro, which may allow *S. aureus* to penetrate across the skin to cause infection.²⁹⁷

Injection of α toxin is lethal to mammals and reptiles, with death occurring within 2 to 5 minutes. Anti- α toxin can be demonstrated in normal individuals,⁵⁵ and antibody to α hemolysin was protective in a mouse model of *S. aureus* pneumonia.²⁶⁶ α Hemolysin also appeared to be a key factor in mortality associated with a rabbit model of MRSA osteomyelitis.⁵⁹ However, because the level of anti- α hemolysin is high in approximately 70% of patients with staphylococcal osteomyelitis and the antibody is also present in children with acute osteomyelitis at the time of admission to hospital, there is doubt regarding a protective role, at least in patients with osteomyelitis.^{37,310}

The other hemolytic toxins, γ , β , and δ hemolysin, also possess hemolytic and cytotoxic activities. Highly cytotoxic, γ hemolysin lyses human neutrophils, and β toxin produces lethal and dermonecrotic effects. Eighty to 100% of adults possess antibody to β hemolysin. LukAB/GH has a reduced cytolytic action on neutrophils compared with γ hemolysin and PVL.⁷⁶ Children with invasive *S. aureus* infections develop high-titer neutralizing antibody to LukAB, but the role of LukAB in pathogenesis of infection or of antibody to LukAB for protection is unclear.³¹⁶ The biologic role of LukED remains unknown, although a variant of this molecule was highly toxic against human neutrophils.²³²

Despite evidence that these toxins are produced during infection, their roles in production of the typical staphylococcal tissue lesion remain unclear.^{24,72} Although toxins likely play important roles in the establishment of infection by interacting with each other and with other biologically active staphylococcal products, the exact mechanisms have not been proved; human infection is not prevented by antitoxin antibody, and virulent staphylococci that lack one or more of these toxins are encountered.²⁹³

An in vitro study showed that α toxin was present in culture supernatants at seven- to ninefold greater concentrations in the USA300 strain compared with the USA400 strain when grown at midexponential and stationary phases of growth.⁴¹ Further studies on how the strain-specific expression of virulence factors during the establishment and course of infection influence the pathology and host response are warranted.

Even though certain hemolysins are toxic to various leukocytes, PVL is the only known extracellular toxin that attacks the leukocyte exclusively.²⁴⁸ It consists of two protein components, LukS-PV and LukF-PV, encoded by the genes *lukS-PV* and *lukF-PV* carried on a bacteriophage.

LukS-PV and LukF-PV assemble to form octameric β -barrel pores in polymorphonuclear leukocytes and macrophages.³² Leukocidin injected into rabbits causes a striking fall in levels of circulating and bone marrow leukocytes, followed by marked granulocytosis; these changes occur without death of the rabbits. Leukocidin interacts with the membrane phospholipid and causes depolarization, increased permeability, and cell death. Local secretion of leukocidin might appear to confer an advantage to the staphylococcus by killing leukocytes and thereby preventing phagocytosis and intracellular killing. Levels of antileukocidin rise rapidly in the course of infection,^{106,150} and some evidence indicates that infants and mothers with high levels of antileukocidin antibody are less likely to contract staphylococcal disease in high-risk epidemiologic situations.²⁰ In one study, a history of furunculosis suggesting a skin infection caused by PVL-producing *S. aureus* isolates was associated with a decrease in complications and mortality for patients with *S. aureus* PVL-associated necrotizing pneumonia.²⁶⁸ Brown and colleagues noted that children who had invasive staphylococcal infections such as osteomyelitis or pneumonia had higher antibody concentrations to PVL at the time of admission to the hospital than children with skin and soft tissue infections, suggesting that PVL antibodies were not

protective against invasive *S. aureus* infections.³⁷ Similarly, high levels of PVL antibody were not found to prevent initial or recurrent skin community-acquired MRSA (CA-MRSA) infections.¹³⁰

In early studies, only a fraction of *S. aureus* isolates recovered from humans carried the PVL genes.²⁵⁷ Interest in PVL greatly increased after reports that *S. aureus* isolates carrying PVL genes were associated with severe furunculosis⁶⁰ and particularly necrotizing pneumonia in children and adolescents that frequently was fatal.^{105,189} Furthermore the independent emergence worldwide of CA-MRSA clones that generally carry the PVL genes led to further studies of the role of PVL in the pathogenesis of *S. aureus* infections.³²² PVL has been of particular interest in association with the USA300 CA-MRSA clone.^{227,229} Using polymerase chain reaction (PCR) the PVL genes have been increasingly detected (*pvl*⁺) in CA-MSSA strains in the United States as well.^{38,140} In children with invasive *S. aureus* osteomyelitis, the presence of the PVL genes was associated with greater local and systemic inflammation, longer extent of fever, greater frequency of positive blood cultures, and more frequent complications such as the development of chronic osteomyelitis or venous thrombosis.^{30,73,212} Pulmonary manifestations were also more frequently observed among children with invasive *S. aureus* infections caused by *pvl*⁺ isolates¹¹¹; *pvl*⁺ strains were isolated almost exclusively among a group of children with staphylococcal pneumonia in one study.⁴² In adults with staphylococcal pneumonia, *pvl*⁺ isolates were associated with increased rates of mortality in one study but were not found to be a significant factor in a larger study of hospital-acquired or ventilator-associated pneumonia.^{203,252} In a multicenter international study, *pvl*⁺ did not predict outcome of *S. aureus* skin and soft tissue infections in adults.³¹⁷ Thus the presence of PVL genes may be a marker for isolates capable of causing more severe disease in some populations of patients but not in others.⁸²

The role of PVL in the pathogenesis of infection in experimental models also remains controversial. The contribution of PVL to severity of *S. aureus* infections has been examined in mice using isogenic *pvl*⁺ or *pvl*⁻ isolates. One study found no difference in lethality for sepsis or abscess volume in a skin abscess model,³²⁸ as well as no difference in the destruction of human neutrophils by the isogenic strains. The investigators concluded that PVL was not a major virulence determinant of CA-MRSA. The other study found *pvl*⁺ isolates caused much greater lung inflammation and necrosis in a mouse acute pneumonia model.¹⁷⁶ PVL was detected in the infected lung tissues. These investigators also discovered that staphylococcal protein A is more highly expressed in *pvl*⁺ strains and postulated that PVL coupled with increased staphylococcal protein A could result in greater tissue inflammation than what is found with *pvl*⁻ strains. A clear role for PVL has been shown in the pathogenesis of necrotizing pneumonia and necrotizing skin infections in a rabbit model.^{69,193} In a rabbit model of osteomyelitis using an isogenic PVL genes negative derivative of a USA300 CA-MRSA isolate (LAC), PVL appeared to play a role in the persistence and extension of infection.⁵⁸ The discrepancy in these studies may be explained by use of different *S. aureus* isolates as well as different models of infection, especially the differential activity of PVL on neutrophils from humans or rabbits compared with murine or simian cells.²⁰¹

Although the exact role of PVL in *S. aureus* infections has not been fully established, treatment measures directed against PVL have been proposed. These measures include the preferred use of protein-inhibiting antibiotics rather than or in addition to bactericidal antibiotics to decrease PVL production,^{75,301} as well as adjunctive administration of intravenous immunoglobulin (IVIG) preparations containing PVL antibody.¹⁰² However, currently there is no evidence that neutralizing PVL or decreasing PVL production affects outcomes.

Enzymes

Staphylococci express a variety of enzymes, including hyaluronidase, nuclease, proteases, lipase, catalase, lysozyme, and lactate dehydrogenase, that might play a role in the spread of infection in local tissues or the establishment of a nidus of infection.

Other biologically active extracellular products, as yet unidentified, undoubtedly are produced by the staphylococcus. The potency and number of these weapons in the armamentarium of the coagulase-positive staphylococcus, in contrast to the small number of extracellular products

associated with the much less virulent coagulase-negative staphylococcus, suggest that the synergistic action of these toxins and enzymes may explain the superior ability of coagulase-positive staphylococci to establish infection and cause tissue necrosis. Several extracellular toxins have been proved to have specific roles in staphylococcal infection or disease: the epidermolytic toxins, TSST-1, and the enterotoxins.

Epidermolytic Toxins

Two biochemically and immunologically distinct exotoxins, epidermolytic toxins A and B (epidermolysins, exfoliatins), can separate adjacent cell layers within the epidermis and cause the various skin manifestations of the staphylococcal scalded skin syndrome (SSSS). These low-molecular-weight (~24,000 Da) protein exotoxins act extracellularly and specifically affect the upper epidermis by cleaving desmoglein-1, an important structural skin protein.^{11,79} are now known.¹¹ Exfoliative toxin D has not been associated SSSS and only occasionally with bullous impetigo but was more commonly found among isolates derived from furuncles and abscesses.^{286,342}

Toxic Shock Syndrome Toxin Type 1

TSST-1 was discovered independently in 1981 by two research groups. It was documented to be an excellent marker for staphylococci associated with vaginal toxic shock syndrome (TSS), in which it correctly identified more than 90% of strains in blinded testing. In experimental animal models, purified TSST-1 can induce the major physiologic changes of TSS: fever, mucous membrane suffusion, renal impairment, hepatic damage, hypocalcemia, lymphocytopenia, and hypotension. TSST-1 can be detected in blood, pus, urine, and tissues during human and experimental model TSS. USA300, the major CA-MRSA clone in the United States, typically does not carry the gene encoding TSST-1.²²⁹ TSS and the role of TSST-1 as a super-antigen are discussed in Chapter 64.

Enterotoxins

More than 20 different staphylococcal enterotoxins (SEA to SEIV) have been identified, most of which cause emesis in primates.^{72,129} The toxins are heat stable and resist boiling. Therefore once sufficient toxin has formed within food, even heating or boiling will not inactivate the toxin. Foods involved in outbreaks of food poisoning frequently have been inoculated by a lesion on the hand of a food handler in situations in which the food is then held at temperatures that allow bacterial growth (between 25°C and 60°C) for some time before the food is served. Foods implicated in particular are ham, salads with starch and mayonnaise, salami, poultry, cream sauces, pastries, and dairy products. The mode of action of enterotoxins is not well understood in part because of the lack of a convenient animal model.²⁰⁷ Intravenous injection of purified enterotoxins in laboratory animals causes hypotension, cardiovascular collapse, and death. The significance of these properties of enterotoxins in naturally occurring human infections is unknown, although they may be linked to clinical syndromes, including TSS. Enterotoxin A often is elaborated with TSST-1 in menstrual-associated TSS, but it also has been identified without TSST-1 in patients with septicemia in whom TSS does not develop. Staphylococcal enterotoxin B, most often isolated in phage group V organisms, is associated with local infections and pneumonia.²¹¹ USA300 strains typically do not contain the genes encoding most enterotoxins but frequently contain molecular variants of enterotoxins K and Q.⁶⁸ In contrast, other successful MRSA clones isolated from either the hospital or community setting carry several of the enterotoxin genes. For example, *seg*, *sei*, *sem*, *sen*, and *seo* were detected from isolates from USA100, USA200, and USA1100 isolates in one study.⁶⁸

Staphylococcus aureus Microbial Surface Components Recognizing Adhesive Matrix Molecules

Bacterial adherence to host tissues is mediated by a number of bacterial surface components or adhesins that recognize and bind to host extracellular matrix and cell surface molecules.¹⁴⁹ The subfamily of adhesins that bind to the extracellular matrix are known as microbial surface components recognizing adhesive matrix molecules (MSCRAMMs). For *S. aureus*, important MSCRAMMs are protein A, fibronectin-binding proteins (A and B), clumping factors A and B (fibrinogen-binding

proteins), and collagen-binding protein (Cna).⁹¹ Many other less well-characterized adhesins also have been identified from the *S. aureus* genome.²⁷³ The MSCRAMMs are linked to bacterial wall peptidoglycan after sortase cleavage of the LPXTG (LeuProXThrGly) motif that is a conserved C-terminal cell wall sorting signal among the adhesins.⁴⁹ Fibronectin-binding proteins play a role in *S. aureus* invasion into endothelial cells.^{30,149} Collagen adhesin protein may contribute to the pathogenesis of *S. aureus* musculoskeletal infections,^{78,246} although there are conflicting animal studies as well as clinical studies in this area.^{151,278} USA300 CA-MRSA isolates do not carry the *Cna* gene, *cna*, yet osteomyelitis and septic arthritis are common CA-MRSA invasive infections in children.^{43,212}

Clumping factor A has been the target for protective immunity in the prevention of *S. aureus* infections, and this approach has been successful in experimental models.³²⁶ The safety and pharmacokinetics of an IVIG preparation enriched for antibody to clumping factor A were established in low-birth-weight infants; however, a large randomized trial did not document efficacy in prevention of staphylococcal infections in this population.²⁸ A monoclonal antibody (tefibazumab [Aurexis]) directed against clumping factor A has undergone preliminary evaluation as adjunctive therapy for *S. aureus* bacteremia in adults, but further development of the product has not occurred.³³³

Regulation

Bacterial pathogenesis is reliant on cell population, density-dependent gene expression. This quorum sensing acts to adjust the production of accessory genes (e.g., virulence genes), depending on the needs of the cell. Studies have shown that in low-density populations, when the bacterial cells are multiplying, accessory genes are either turned off or expressed at a low level to the advantage of other genes, such as genes involved in cell wall formation. In high-density bacterial populations, expression of the accessory genes is increased. The accessory gene regulator, *agr*, is genus specific, and the effector molecule is a regulatory RNA molecule, RNAIII. Many staphylococcal toxins and virulence factors are under the regulation of *agr*, and *agr* dysfunction is associated with reduced clearance of MRSA infection by vancomycin.^{2,15,36,95,228} The staphylococcal accessory regulator, *sarA*, also functions as a global regulator in *S. aureus*. The *sar* locus produces three overlapping transcriptional units (*sarB*, *sarC*, and *sarA*), and the effector peptide, *SarA*, is a DNA-binding protein that functions as a transcriptional regulator. Both RNAIII and *SarA* have been shown to influence *S. aureus* virulence in animal models of infection. In addition to *agr* and *sarA*, several other factors have been described that affect accessory gene regulation.²⁷ Thus the complex network of regulatory operons that act on each other and/or directly on specific genes is not completely understood.

Staphylococcal Small Colony Variants

Small colony variants of *S. aureus* are isolates with atypical colony morphology, decreased hemolysis and pigmentation, decreased growth rate, and unusual biochemical characteristics that result in difficulty isolating and identifying these organisms.³²⁴ Small colony variants also have been implicated in persistent and recurrent *S. aureus* infections, including osteomyelitis,²⁶⁰ brain abscesses, and pulmonary infections in patients with cystic fibrosis.^{156,284} Small colony variants can persist intracellularly, are often more resistant to antibiotics than the parent strain and antibiotics that penetrate into cells (e.g., rifampin), and do not activate innate host systems to the same degree as wild-type phenotypes, which helps to explain their successful intracellular persistence.^{261,318} In one model of chronic osteomyelitis, some antibiotics induced small colony variants and only rifampicin was effective at reducing bacterial loads.³¹⁹

Staphylococcal Cassette Chromosome *mec*

The staphylococcal cassette chromosome *mec* (SCC*mec*) is a region spanning between 20 and 70 kb located approximately 30 kb downstream of the chromosomal origin of replication. SCC*mec* contains the *mecA* gene encoding a penicillin-binding protein (PBP2a or 2') with poor affinity to β -lactam antibiotics, allowing essential functions of cell wall formation to proceed in the presence of β -lactam antibiotics. The *mecA* gene is regulated by *mecR1* and *mecI* where activated *mecR1* (signal transducer) inactivates *mecI* (repressor) through site-specific proteolytic

cleavage, thereby initiating production of PBP2'. In vitro studies have suggested that the β -lactamase regulators *blaR1* and *blaI* may also be effective regulators of *mecA*.²¹⁹

The SCCmec classification systems are based on several genetic elements including the class of *mec* and the *ccr* genes, which are recombination genes involved in the mobility of the genetic cassette. Other elements that may be present are IS431, IS1272, Tn554, pUB110, and pT181. SCCmec types II and III also contain other antibiotic resistance genes such as *tet* (tetracycline resistance). All strains contain a J(un)k region of variable size and composition. Several schemes for SCCmec typing have been published.^{170,242,243} Historically nosocomial MRSA isolates contained the SCCmec types I to III, and when community isolates were first described, three new types—IV, V, and VI—were introduced. Two more SCCmec types have been described, tentatively named VII and VIII. The smaller size (<30 kb) of SCCmec IV to VI is thought to explain an increased mobility between strains. Because the community strains have been brought into the health care setting, SCCmec typing cannot be used to predict whether an infection is health care or community related.^{110,128,285}

TYPING METHODS

Staphylococcal strains were historically characterized by bacteriophage typing (World Health Organization method).²¹ *S. aureus* isolates are susceptible to lysis when exposed to bacteriophages. Bacteriophage typing has been used primarily as an epidemiologic tool for identifying related strains in epidemics. Staphylococci of phage group 80/81 were widespread during the pandemic of staphylococcal disease in the late 1950s. At present, a wide variety of phage types are involved in staphylococcal disease.²⁷²

In the 1990s pulsed-field gel electrophoresis (PFGE) became the gold standard for strain typing utilized by both reference and research laboratories.³¹¹ The method is reliable and reproducible, and the use of digital imaging and band analysis has enhanced the quality of interstrain and interlaboratory comparisons. The Centers for Disease Control and Prevention (CDC) used the PFGE method to define and interrelate *S. aureus* clones and designated 11 staphylococcal clones circulating in the United States as USA100 to USA1100.²¹⁵

Multilocus sequence typing (MLST) is a nucleotide sequence-based method adapted from multilocus enzyme electrophoresis (MLEE). In MLST typing the alleles at each locus of seven housekeeping genes (*arcC*, *aroE*, *glpF*, *gmk*, *pta*, *tpi*, and *yqiL*) are determined through PCR amplification, nucleotide sequencing, and submission of sequence data via computer website to the MLST database (<http://pubmlst.org/saureus>).⁸⁰ In this database, strains can be compared with strains submitted by other investigators, and within-laboratory comparisons with control strains thus have become obsolete.

spa typing is a single-locus sequence method, based on the polymorphic X or the short sequence repeat (SSR) region of the protein A gene.²⁹⁰ *spa* typing has some advantages over PFGE in terms of speed, interpretation, and exportability, the main limitation being the single-locus-based design.¹²¹ Less commonly used methods include repetitive-element PCR (rep-PCR), restriction fragment length polymorphism (RFLP), and toxin typing. Reductions in the overall cost and advancements of techniques has led to an increased application of whole genome sequencing (WGS) in both clinical and research settings, enabling more detailed comparisons between isolates compared to previous methods.^{182,202}

Staphylococcus aureus Clones in the Hospital and in the Community

Of the methods mentioned earlier, MLST has been especially useful in dividing *S. aureus* strains into lineages (or clonal clusters). Frequently these clones are described by their sequence type followed by the SCCmec type (e.g., ST8-IV). Most human *S. aureus* strains belong to 1 of 10 independent lineages. Five major clonal clusters (CC) that have been described to contain a majority of the human MRSA strains are CC5, CC8, CC22, CC30, and CC45. Of these, MRSA clones within the CC5 and CC8 clusters have been recognized as the main causes of hospital outbreaks worldwide.⁵³ Examples of widespread hospital MRSA clones

are EMRSA15-ST22, EMRSA16 (ST36-II), the Archaic (ST250-I or 247-I), the Pediatric (ST5-IV), and the Brazilian (ST239-III) clones.¹⁰⁸

Although a few hospital MRSA clones have circulated around the world, genetically distinct community clones have been reported from different geographic areas. Commonly these strains contain the smaller SCCmec elements, type IV or V.²⁷¹ Why these different clones emerged in parallel at this point in time is unknown.

In the United States, the currently most common community MRSA clone is USA300-ST8. USA400-ST1, originally described as MRSA strain MW2, which caused four pediatric deaths in Minnesota and North Dakota, was commonly observed in the Midwestern states in the early 2000s.¹² USA300 is the most frequently reported strain causing community-acquired disease in both pediatric and adult settings in the United States.⁶⁵ Like many other epidemic strains, it has been associated with a spectrum of disease presentations ranging from simple skin and soft tissue infections^{157,162} to severe sepsis syndrome,^{6,112} sometimes with fatal outcome. USA300 is a highly virulent strain that has been distributed over the continent and has become the most prevalent cause of community-acquired and community-onset health care-associated infections in less than a decade in the United States as well as in many other countries on different continents.^{138,229,238} It has also become the most common source of hospital-acquired *S. aureus* infection in many hospitals, where it has acquired one or more antibiotic resistance markers.^{66,110,139,285}

MLST typing has enabled the ancestry of many of these clones to be traced phylogenetically. For example, phage type 80/81 (ST30-MSSA) was epidemic in the 1960s and is the likely ancestor to the widely circulated Southwest Pacific clone ST30-MRSA-IV, which has been successful both as a colonizer and as a cause of diseases ranging from skin and soft tissue infections to invasive manifestations.²⁷² Similarly the USA300 (ST8-MRSA-IV) clone is postulated to have descended from an archaic ST8-MSSA.⁸¹

GENOMES

The list of current or completed *S. aureus* genome sequencing projects, submitted to the National Institutes of Health (NIH) genomes database (www.ncbi.nlm.nih.gov), contains more than 100 isolates and is continuously increasing. The sequenced genomes include CA-MRSA clones from the United States (e.g., MW2,¹⁶ FPR3757,⁷⁰ and TCH 1516¹³³). Among hospital-associated MRSA strains, genomes of the first reported MRSA clones, *S. aureus* COL,¹⁰³ as well as EMRSA-16,¹⁵² N315, and Mu50,¹⁷⁵ are available. In addition, methicillin-susceptible isolates such as strains 476¹³⁷ and NCTC 8325¹⁰⁴ have been well defined.

Genome sizes range from 2.7 to 3.1 Mb, and the structures of the chromosomes are conserved. The core genome (the part of the genome that is the same in all strains) represents approximately 75% of the genome.¹⁹⁰ The biologic function remains unknown for at least a third of the predicted proteins. In the future the knowledge gained from these ongoing sequencing projects and analyses of the resulting large datasets will provide a deeper insight into the genetic differences of *S. aureus* strains and may give clues into the strain-specific causes of disease versus colonization, suggest candidate genes for potential vaccine or drug targets, or provide information into the acquisition of antibiotic resistance or virulence factors. For example, a comparative genome project of vancomycin-resistant strains provided proof that the vancomycin-resistant isolates reported to date in the United States all represented new acquisition of transposon Tn1546 from *Enterococcus* spp. and also identified a change in a gene important for uptake of foreign DNA, which may have facilitated the genetic exchange.¹⁷¹ In another study using whole-genome sequencing, absence of patient-to-patient spread of sterile-site infection within the hospital was demonstrated.²⁰²

EPIDEMIOLOGY

S. aureus isolates are responsible for both sporadic infections and epidemics of varying extent ranging from the intrafamily outbreaks of staphylococcal disease commonly encountered to large and often prolonged hospital-associated outbreaks, such as those emanating from a neonatal

nursery or a surgical service. Epidemic spread of staphylococci of phage type 80/81 was so widespread worldwide in the period encompassing the mid-1950s through the early 1960s that it constituted a pandemic. Researchers have suggested that a few “epidemiologically virulent” strains, such as 80/81, are particularly capable of spreading widely and causing disease. Robinson and colleagues²⁷² concluded that descendants of 80/81 have acquired methicillin resistance to emerge as a CA-MRSA clone, closely related to the Southwest Pacific ST30 clone. Because we are largely ignorant of the factors responsible for pandemic spread, we cannot prevent or predict recurrence.

Staphylococci may be transmitted by multiple routes, including contact with infected persons, contact with asymptomatic carriers, airborne spread, and contact with contaminated objects. Of these mechanisms, contact with a person who has a staphylococcal lesion appears to be particularly important in the spread of staphylococci. Persons with open draining lesions disseminate organisms into their environment and to others via direct contact. In a hospital, staphylococci may be spread from an infected patient to another on the hands of caretakers, such as physicians or nurses. Hospital personnel with mild or unapparent lesions, such as sties, furuncles, or paronychia, may themselves spread organisms. In family and small community outbreaks, multiple secondary cases can occur and frequently can be traced to an individual with a draining lesion. Secondary cases tend to appear for months after the initiating case within these small epidemiologic units.²⁹⁹ Staphylococci also may be spread by asymptomatic carriers who have staphylococci in one or more body sites, including the nose, skin, hair, nails, axillae, and perineum.

At any one time, up to 30% of individuals are colonized in their anterior nose with *S. aureus*.¹⁶⁸ The rate of nasal carriage of MRSA appears to have increased. Nasal carriage of MRSA was 0.8% in 2001²³⁶ and 9% in 2004⁵⁷ for children seen in an emergency center in Nashville, Tennessee. For children admitted to a hospital in Corpus Christi, Texas, in 2005, the rate of MRSA colonization was 22%.⁸ In 2004 to 2005, an average of 2.6% (range, 0% to 9%) of children in 11 different practices in the St. Louis metropolitan area was colonized with MRSA in the nose.⁹⁷ Why nasal colonization of children by CA-MRSA has increased over the past decade is unclear but is likely related to unique properties of the major CA-MRSA clone USA300.⁷⁰ Actually for children with skin and soft tissue infections, CA-MRSA colonization of the groin is more commonly detected than is nasal carriage.^{99,161}

Detailed studies have been performed to delineate factors regulating the carrier state and its establishment and perpetuation, as well as factors responsible for dispersion of organisms from carriers. Asymptomatic carriers may be a source of disease for themselves and others. For example, a wound infection appears to be more likely to develop in a hospitalized patient who becomes a carrier than in a noncarrier.³³⁴ Much attention has been devoted to detecting and attempting to treat nasal carriers of staphylococci; however, studies of nursery outbreaks have indicated that nasal carriage is not as important as is hand transmission in the dispersal of staphylococci.³³⁷ Transmission by hand contact can be minimized by effective hand washing.¹⁰⁷ The problem of hair carriage of staphylococci in operating room personnel has been minimized by using improved head coverings.

Staphylococci are widespread in the environment and can be cultured from clothing, carpets, toiletries (e.g., hairbrushes, razors), pets, and virtually all environmental surfaces, especially in the bathroom.²³⁰ Airborne dissemination of organisms is possible, particularly in operating rooms with poor ventilation and heavy traffic; improved methods of ventilating operating rooms may have reduced the sepsis or colonization rate. Environmental staphylococci may serve as an important reservoir, but direct human-to-human transfer probably is a much more important means of transmission in epidemic situations than is airborne spread or contact with contaminated objects. This means of transmission is particularly true for spread of CA-MRSA among athletes.¹⁶⁶ Furthermore USA300 appears to be especially able to spread among household members, in part related to increased contamination of environmental surfaces.^{225,320} Molecular methods of typing offer adjunctive information useful in characterizing strains involved in outbreaks.^{71,80}

Few studies have reported the incidence of *S. aureus* infections in children. Over a 12-month period in 2004–05 in San Francisco, Liu

et al.¹⁹⁶ reported the annual incidence of community-onset disease per 100,000 was 227 for children younger than 5 years, 100 for children 5 to 14 years old, and 284 for individuals 15 to 24 years old. The incidence of hospitalization per 100,000 for children with staphylococcal infections in California for the years 1985–2009 varied between 26 for children 6 to 9 years old and 83 for children 1 to 2 years of age.¹¹⁸ The incidence of MRSA infections per 1000 patient-visits at Children’s National Medical Center in Washington, DC, increased significantly from 0.93 in 2004 to a peak of 5.34 in 2007 but then decreased 5% per year through 2010.²⁹⁶ The CDC Active Bacterial Core Surveillance study found the incidence of invasive CA-MRSA infection per 100,000 children increased from 1.1 in 2005 to 1.7 in 2010.¹⁴³ In Canada from 2000 to 2006, the incidence of *S. aureus* bacteremia in children younger than 19 years was 6.5 per 100,000; 52% of these patients had a significant underlying disease and 56% had the onset of infection in the community.³²³ Since these studies are based on culture results, and many skin and soft tissue infections especially are not cultured, undoubtedly the overall incidence of *S. aureus* infections in children is underestimated.

The neonatal nursery has been an area of particular concern in the transmission of *S. aureus*. During the pandemic of strain 80/81 disease, outbreaks of serious neonatal disease were commonplace, high colonization rates were found in infants on discharge from the nursery, and the subsequent incidence of disease in some outbreaks was as high as 50% to 70%. Skin disease and infant and maternal mastitis usually appear within 1 to 4 weeks after discharge. Staphylococcal pneumonia, far more common during that period than at present, may not be seen for months after delivery, even though the infecting strain was acquired in a hospital. During the experience with strain 80/81 disease, a particularly high staphylococcal attack rate was seen in the families of colonized infants. The same epidemiology has been noted for the USA300 CA-MRSA clone that has been associated with staphylococcal infections in otherwise healthy newborns up through 30 days of life.⁸⁹ One study reported that 20% of infants with an *S. aureus* infection had a mother with a concomitant (proved or presumed) infection.⁸⁹ In a study of infants up to 30 days of age with community-onset *S. aureus* infections, the infecting strain in the neonate was the same as a nasal *S. aureus* strain recovered from the mother in eight of 34 (24%) mother-neonate pairs.⁸⁸ This suggests that maternal nasal colonization is not the sole source of *S. aureus* isolates causing infection in their otherwise healthy full-term neonate. In other studies, *S. aureus* colonization of infants was more likely to be related to horizontal than vertical transmission from the mother.¹⁴⁸

Various control measures were used successfully to terminate individual outbreaks during the 1980s. Measures to protect the infant from colonization and subsequent development of disease by establishing a barrier at the site of initial colonization included hexachlorophene bathing, application of antibiotic ointment to the umbilicus and circumcision site, and application of an antiseptic dye to the umbilicus. Another approach, deliberate colonization of the umbilicus with an interfering “avirulent” strain, was successful in controlling several epidemics but itself has caused skin disease and, in one case, fatal septicemia.²⁸⁹ Hexachlorophene bathing became a widespread practice during the period in which nosocomial staphylococcal infections were declining.^{107,254}

After approximately a decade of using hexachlorophene, researchers recognized that cutaneous absorption of hexachlorophene could result in potentially toxic hexachlorophene blood levels in infants, particularly premature ones, subjected to repeated daily baths over time. Brainstem abnormalities associated with the use of hexachlorophene were demonstrated in premature infants. For these reasons, controls were placed on the sale of hexachlorophene, and its routine use was discouraged in 1973. In one neonatal nursery outbreak of MRSA, the use of 0.3% triclosan (Bacti-Stat) was associated with cessation of an outbreak.³⁴⁴

Patterns of crowding of infants and understaffing contribute to outbreaks. Active clinical and bacteriologic surveillance and cohorting of infants may be effective in reducing outbreaks.^{18,120} However, mandated active surveillance for MRSA nasal carriage during 5 years among neonates in the NICU did not appear to alter serial point prevalence of MRSA nasal colonization (4.2%) in 10 Chicago NICUs.²⁰⁴

S. aureus bacteremia related to intravenous catheters and *S. aureus* infections of prosthetic devices are common.^{44,208,209} In particular,

methicillin-resistant staphylococci are responsible for widespread nosocomial outbreaks of disease in hospitals.^{31,39,56,62,83,167,281,304,332}

HOST DEFENSES

S. aureus is ubiquitous in the environment, and approximately 30% of the population are carriers. A major defense against staphylococcal infection is intact skin. Minor wounds frequently become colonized and infected and serve as portals to deeper, more significant staphylococcal infection. In some cases, the integumentary infection may be of major importance; in others, minor skin punctures may serve to introduce infection to distant internal sites. Burns, varicella virus and cutaneous herpesvirus infections, insect bites, minor lacerations or abrasions, primary skin diseases (e.g., atopic eczema), epidermolysis bullosa, and surgical wounds are important portals of entry for staphylococci. A deficiency in peptides (defensins and cathelicidins) important for innate immunity of skin against *S. aureus* has been shown in skin specimens from patients with atopic dermatitis and likely contributes to the increased susceptibility of the skin to *S. aureus* infections in these patients.^{169,244} In hospitalized patients, intravenous needles and catheters may be sources of staphylococcal infection.^{208,209}

Foreign bodies reduce local resistance to staphylococcal engraftment and are important in the pathogenesis and perpetuation of infection. Noteworthy foreign bodies are cerebrospinal fluid shunts, prosthetic cardiac valves, nonabsorbable sutures, vascular prostheses (including arteriovenous shunts for hemodialysis), orthopedic prostheses, nails, and wires. In neonates, the umbilicus and circumcision sites, which may be colonized within the first few hours of life and from which both local and distant infections may be established, are important portals of entry.

Viral respiratory diseases such as measles and influenza^{119,255} predispose to development of pulmonary infection, again predominantly by damaging the integrity of the barrier at the portal of entry. In an animal model, differences in the ability of *S. aureus* strains to cause secondary bacterial pneumonia after influenza can be demonstrated.¹⁴² Disruption of the respiratory epithelium and impairment of ciliary motion and other local defenses may allow secondary staphylococcal invasion. In a CDC study of complications of hospitalized children with influenza, *S. aureus* was the most commonly identified bacteria causing coinfections.⁶⁷

Once the integumentary barrier has been breached, the polymorphonuclear leukocyte appears to be the most important line of defense. Successful phagocytosis involves chemotaxis, opsonization, and intracellular killing. The incidence of difficulty with staphylococcal infection is highest in patients with defects in this area of host defense.^{90,340} Granulocytopenia of any origin predisposes to the development of infection, particularly with the host's endogenous bacteria, including staphylococci.¹⁷ Krishna and Miller have extensively reviewed the innate and adaptive immune response of the skin to *S. aureus* infections.¹⁷³

Once the staphylococcus and the leukocyte are close to one another, opsonization of the bacterium must proceed for phagocytosis to occur. Two systems for opsonization of staphylococci have been described. Serum from normal adults has good opsonic activity when unheated but is generally inactive after heating at 56°C for 1 hour. The heat lability of normal opsonin and the observation of normal or only slightly decreased opsonic activity in unheated sera from patients with agammaglobulinemia³³⁸ indicate that the major opsonin is complement. A few sera, generally from patients convalescing from serious staphylococcal disease, contain heat-stable opsonins, presumably antibody directed at the staphylococcal cell wall components.¹⁷⁹ Therefore either complement or antibody can provide opsonins for staphylococci; specific antibody is helpful but not required. The clinical correlate to these observations may be found in patients with defective defenses; patients with agammaglobulinemia and defective antibody generally have more severe problems with organisms other than staphylococci, whereas patients with deficiencies in complement components have been reported to have repeated and severe staphylococcal infections.^{4,9,10,92,226,251}

Once the bacterium has been ingested, intracellular killing proceeds normally. Coagulase-positive staphylococci can survive within polymorphonuclear leukocytes for a considerably longer period than can

coagulase-negative organisms.²²² Prolonged intracellular survival may be an important virulence factor separating coagulase-negative from coagulase-positive strains and may provide a mechanism whereby surviving organisms may be carried to distant body sites to establish metastatic foci of infection. A number of *S. aureus* exotoxins outlined earlier, such as PVL, contribute to the ability of *S. aureus* to evade human neutrophils. In addition, many *S. aureus* genes are regulated upward or downward after exposure to human neutrophils and there are differences in gene expression among various strains in response to human innate host response that might account for differences in the ability of the isolate to cause infection.³²⁷

Patients with chronic granulomatous disease of childhood have an inborn error in intraleukocytic killing of catalase-positive bacteria and fungi. These patients have an early onset of recurrent purulent infections of the skin, subcutaneous tissue, lungs, and reticuloendothelial organs, particularly the liver, that often are caused by *S. aureus*.²⁶⁵ Staphylococcal infections are also characteristics of hyper-IgE syndrome and leukocyte adhesion deficiency syndromes. Neutrophil disorders are discussed in detail in Chapter 2.

In contrast to the primacy of polymorphonuclear defense against staphylococci, evidence for an important role of specific humoral and cellular immunity in host defense against staphylococci is either lacking or contradictory. Specific antibody is not required for opsonization of unencapsulated strains of staphylococci. The opsonic activity of serum from patients recovering from staphylococcal endocarditis or other serious disease is greater than that of otherwise normal persons.^{179,335} Despite the presence of humoral antibodies to cell wall teichoic acids and to various toxins and enzymes, which are found regularly in those convalescing from serious staphylococcal infection, the patient remains susceptible to recurrence of infection with the same strain of staphylococci. Staphylococcal infections generally occur and progress in the presence of some degree of humoral immunity. Specific antibody to one or more staphylococcal components or products does not protect against infection.

Clinical evidence from patients with deficient cell-mediated immunity (combined immunodeficiency, thymic aplasia, Nezelof syndrome) suggests that staphylococcal infections are not among the most important pathogens in these patients. However, in an animal model, interleukin-17 production by local T cells is important for host defense against *S. aureus* cutaneous infections.⁵²

Present evidence therefore suggests that intact local skin and mucous membrane barriers are the most important defense against the establishment of staphylococcal infection. Once infection is established, an intact polymorphonuclear response is essential for containment of the infection and clearance of the organisms.

Genomic studies are leading to a greater understanding of the host response to *S. aureus* and may lead to novel treatment or prevention modalities. Using microarray techniques to describe the host immune transcriptional profile in children with primarily invasive *S. aureus* infections, Banchereau and colleagues¹⁹ found an overexpression of innate immunity and hematopoiesis genes and an underexpression of genes associated with adaptive immunity. Differences in gene expression were seen between children with musculoskeletal infections and those with pneumonia. Of interest, patients with osteoarticular infections displayed overexpression of transcripts linked to coagulation of blood that might relate to the venous thromboses that may occur with *S. aureus* osteomyelitis.¹¹³

PATHOGENESIS

Staphylococci cause disease by two mechanisms: direct invasion of tissues with liberation of toxins, which may have effects at sites distant from the focus of infection, and colonization. The hallmark of a staphylococcal lesion is the abscess. Local tissue destruction at the site of inoculation is followed rapidly by hyperemia and a vigorous inflammatory response marked by the accumulation of large numbers of polymorphonuclear leukocytes. Tissue necrosis in the center of the lesion occurs next. At the site of intensive hyperemia surrounding the lesion, a fibrin wall is formed. Liquefaction necrosis occurs centrally; the mature lesion consists of a fibrin wall surrounded by inflamed tissues enclosing a central core

of pus consisting of organisms and leukocytes. Live bacteria may persist within these lesions for a considerable period of time. As pus accumulates, it may drain toward the skin surface or into adjacent tissues, where it forms sinus tracts and secondary abscesses. In the presence of an intact host inflammatory response, this type of reaction may be seen in diverse areas, including the skin and subcutaneous tissues, lymph nodes, joints, kidney, liver, parotid glands, muscles, lungs, and long bones.

In addition to local extension, *S. aureus* may disseminate hematogenously from this focus of infection, even from abscesses that are trivial in size. Hematogenous dissemination may result in infection of bones, joints, and heart valves. Given the ubiquitous nature of staphylococci, skin and wounds, which are the usual ports of entry, appear to be remarkably resistant to infection. This natural resistance is affected dramatically by the presence of foreign bodies within the wound, such as sutures and bits of soil or gravel. Natural resistance also is affected by the tissue compromise that occurs after ecchymosis or hemorrhage and by vascular insufficiency. Poor personal hygiene likewise predisposes to development of staphylococcal skin infection. Moist, macerated skin is invaded more easily and thus contributes to the increased frequency of staphylococcal skin infection in intertriginous areas and in tropical climates.

Toxicogenic staphylococcal disease includes staphylococcal scalded skin syndrome, TSS, and staphylococcal food poisoning. Toxin can be elaborated from *S. aureus* isolates that are colonizing sites without a specific site of infection but leading to TSS. The major manifestations of these diseases are caused by the effects of specific toxins. Clinical manifestations of infections caused by *S. aureus* in children are discussed in multiple chapters, and the reader is referred to the specific infection of interest.

DIAGNOSIS

The diagnosis of significant staphylococcal infections should be pursued with vigor. Collections of pus, whether superficial or deep, should be aspirated or drained surgically for diagnostic and therapeutic purposes. Gram stain and culture should be performed. An aggressive approach to the diagnosis of osteomyelitis by bone aspiration and bone biopsy or surgical drainage provides an etiologic security that is helpful during the prolonged treatment phase that necessarily follows. When infection is associated with a foreign body, such as a central catheter or ventriculoperitoneal shunt, removal and culture of the foreign body help in determining the etiology and removal is almost always required for successful resolution of infection.

When possible, at least two blood cultures should be obtained before starting therapy for all serious infections. One need not wait for fever spikes or delay therapy to obtain specimens. Blood cultures frequently are negative in serious staphylococcal infection, a fact that demonstrates the need for performing other cultures. Blood cultures are positive in most cases of staphylococcal endocarditis, approximately half the cases of osteomyelitis and septic arthritis, and less than half the cases of pneumonia and deep tissue abscesses. PCR may detect evidence of *S. aureus* in normally sterile body fluids such as pleural fluid.²⁶ A number of molecular tests are available to rapidly identify MRSA once isolated (or growing in blood culture bottles) in the microbiology laboratory as well as to detect MRSA colonization in patients at the time of hospital admission.³²¹

Measurement of nonspecific indicators of inflammation (e.g., erythrocyte sedimentation rate and C-reactive protein), although of limited value in diagnosis, can be helpful in monitoring the clinical course of infection and response to intervention. Accurate, sensitive serologic methods for making a diagnosis of serious staphylococcal infection are not available.

Enterotoxins can be identified by a variety of methods. Immunoassay is used routinely but may lack the sensitivity required to detect levels seen in staphylococcal food poisoning. DNA oligonucleotide probes are highly sensitive, but their clinical utility is limited by the identification of nonexpressed genes.²⁴¹

TREATMENT

Successful treatment of staphylococcal infection depends on adequate drainage of collections of pus and the rational use of antibiotic therapy.

Strategies for clinical management of MRSA infections, including those in children, are outlined in guidelines published by the Infectious Diseases Society of America.¹⁹⁴ Staphylococcal infections have a particular tendency to persist and recur; for these reasons, prolonged antibiotic therapy usually is required for all but minor infections. Surgical drainage is extremely important and, in some patients with minor superficial abscesses, may be all that is required.^{51,77} In one study an abscess less than 5 cm in diameter was associated with successful outcome after incision and drainage regardless of whether the antibiotic administered was active against the isolated pathogen, which was CA-MRSA.¹⁸⁴ In other studies the size of the abscess was not associated with outcome.⁵¹ But for some infections, a period of antibiotic therapy after surgical drainage better ensures that the infection has been contained. In an adult study, antibiotics active against CA-MRSA were associated with significantly greater cures than agents not active against CA-MRSA in patients who had undergone incision and drainage of skin and soft tissue infections.²⁷⁶ Failure to provide surgical drainage is an important reason for persistence or recurrence of organisms. Antibiotics cannot be expected to penetrate into the avascular center of abscess cavities. When abscess cavities are undrained or when antibiotic therapy is discontinued before an area is sterilized, live bacteria may persist and disseminate to cause later recurrence at that site or distant sites. After incision and drainage, adjunctive antibiotics are recommended for patients with underlying conditions or with immunosuppression; multiple sites of infection; rapidly progressive lesions or lesions associated with cellulitis; abscesses located on the face, hand, or perineum; young children (<1 to 2 years old); or those patients whose condition has not improved with incision and drainage alone.¹⁹⁴

For moderate to severe staphylococcal infection, the patient should be hospitalized initially for intravenous therapy. This strategy ensures peak antibiotic levels, which may allow greater penetration into relatively avascular areas. Once the patient is afebrile, has a negative blood culture, and there is definite evidence of clinical improvement, therapy can be completed with home administration of antibiotics or with oral agents, as deemed appropriate by the treating physicians.

Antibiotics for *Staphylococcus aureus* Infections

Since the mid 1960s, the vast majority of *S. aureus* isolates from most sections of North America and Europe have been penicillinase producers and, therefore, penicillin resistant. When *S. aureus* is likely to be the cause of infection, the most appropriate agents to administer for empirical treatment of infections with onset in the community in normal children are based on the relative frequency of CA-MRSA isolates in the particular community. In areas where CA-MRSA isolates are not a concern, treatment with a penicillinase-resistant penicillin or cephalosporin should be initiated before isolation of bacteria and susceptibility testing (Table 80.2). Methicillin-resistant organisms cannot be treated adequately with β -lactam antibiotics, including cephalosporins except for ceftaroline and ceftobiprole. In some locations, methicillin resistance is widespread in community isolates and thus alternative agents (see later discussion) are indicated for empirical treatment. When a penicillin-resistant organism that is susceptible to oxacillin is isolated (MSSA), the semi-synthetic penicillinase-resistant penicillins or cefazolin are the drugs of choice.^{187,267} Oxacillin, nafcillin and cefazolin are available for parenteral use. Dicloxacillin and cephalexin are the preferred oral agents.

If clinical response appears to be slow, nothing is to be gained by switching to another antibiotic within the same category; instead, microbiologic data should be reviewed and the dose of antibiotic rechecked to be certain it is correct, the patient is reassessed to be certain all sites requiring drainage have been addressed, and compliance with therapy is assured, especially if the antibiotics have been administered orally.

The cephalosporin antibiotics are active against penicillinase-producing staphylococci and cause less irritation of veins with intravenous infusion than do penicillinase-resistant penicillins. A potential disadvantage lies in their broader spectrum of activity, which may promote superinfection with cephalosporin-resistant, gram-negative organisms in a debilitated patient with serious staphylococcal disease. Cephalosporins have been advocated widely for use in patients allergic to penicillin, but because of considerable cross-reactivity, they should be used

TABLE 80.2 Therapy for Staphylococcal Infections in Infants and Children (Excluding Neonates)

Drug	Oral (Mild to Moderate Infection)		Parenteral (Moderate to Severe Infection)	
	Children <40 kg	Children >40 kg and Adults	Children <40 kg	Children >40 kg and Adults
Penicillins				
Oxacillin			150–200 mg/kg/24 h in 4–6 doses q4–6h IV	4–8 g/24 h in 4–6 doses q4–6h IV
Nafcillin			150–200 mg/kg/24 h in 4–6 doses q4–6h IV	4–8 g/24 h in 4–6 doses q4–6h IV
Cloxacillin	50–100 mg/kg/24 h in 4 doses	2–4 g/24 h in 4 doses		
Dicloxacillin	25–75 mg/kg/24 h in 4 doses	1–2 g/24 h in 4 doses		
Cephalosporins				
Cefazolin (Ancef, Kefzol)			75–100 mg/kg/24 h in 3 doses q8h	4–6 g/24 h in 3 doses
Cephalexin (Keflex)	25–100 mg/kg/24 h in 4 doses	1–4 g/24 h in 4 doses		
Cefadroxil (Duricef, Ultracel)	30 mg/kg/24 h in 2 doses	1–2 g/24 h in 2 doses		
Other Agents				
Erythromycin	35–50 mg/kg/24 h in 4 doses	1–2 g/24 h in 4 doses		
Clindamycin	25–40 mg/kg/24 h in 3 doses	600–1200 mg/24 h in 3–4 doses	30–40 mg/kg/24 h q6–8h IV	600–3000 mg/24 h q6–8h IV
Vancomycin			40–60 mg/kg/24 h q6h drip over 1 h or by continuous IV drip	1–2 g/24 h q6h over 1 h or by continuous IV drip
Linezolid	10 mg/kg/dose q8h ^a	10 mg/kg/dose q12h ^b	10 mg/kg/dose q8h ^a	10 mg/kg/dose q12h ^b
Doxycycline	2–4 mg/kg/24 h 1 or 2 doses >7 years of age	100–200 mg/24 h		
Trimethoprim–sulfamethoxazole	8–12 mg/kg/24 h of TMP in 2 doses	160 mg of TMP q12h		

Refer to the 2015 Red Book for anti-staphylococcal antibiotic dosing for the neonate.

^aDose for children <12 y.

^bDose for children ≥12 y, not to exceed 600 mg/dose.

IV, intravenously; TMP, trimethoprim.

Modified from American Academy of Pediatrics. Table 4.2: Antibacterial drugs for neonates. In Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th edition. Elk Grove Village, IL: American Academy of Pediatrics; 2015:882–883.

extremely cautiously, if at all, in patients with a clear history of serious penicillin allergy or anaphylaxis. Among this group of antibiotics, cefazolin is the agent of choice for parenteral use.²⁵³ It is well tolerated and can be administered every 8 hours intravenously. Serum concentrations of cefazolin are higher, and effective tissue levels appear to be easier to attain. Cefazolin also is associated with less bone marrow suppression than nafcillin or oxacillin. The efficacy of the second- and third-generation cephalosporins against *S. aureus* is reduced. Therefore, these drugs, especially cefotaxime, ceftriaxone, and cefuroxime, should be given in addition to specific antistaphylococcal agents if *S. aureus* is strongly suspected. Clindamycin and trimethoprim-sulfamethoxazole are alternative agents for patients who are seriously allergic to or intolerant of β -lactam antibiotics.^{14,84,163} Clindamycin is an important option for treating invasive *S. aureus* infections but should only be considered if or when blood cultures are negative and endovascular infection, such as infective endocarditis, is not a concern because clindamycin is a bacteriostatic agent. In one study using a large insurance database for assessing outcome of large numbers of children with skin and skin structure infections (not *S. aureus*-specific infections), trimethoprim-sulfamethoxazole and cephalexin were more likely than clindamycin to be associated with treatment failures and recurrences.²⁹⁹ However, in a large randomized trial, clindamycin and trimethoprim-sulfamethoxazole were found equivalent in the treatment of uncomplicated skin infections including cellulitis and abscesses (>5 cm in adults but smaller for children); abscesses were surgically incised and drained.²²⁴ Almost 30% of the patients enrolled in this study were less than 18 years old and 19% were less than 9 years old.

The β -lactam resistance of MRSA is caused by the production of a novel penicillin-binding protein (PBP) designated PBP-2', which, unlike the intrinsic set of PBPs (PBP-1 to PBP-4) of *S. aureus*, has remarkably

reduced binding affinities to β -lactam antibiotics. Despite the presence of otherwise inhibitory concentrations of β -lactam antibiotics, MRSA can continue to synthesize cell walls solely through the uninhibited activity of PBP-2' on 2α .^{165,214} PBP-2' is encoded by the *mecA* gene, which is carried by a unique mobile genetic element integrated into the *S. aureus* chromosome designated SCC_{mec}.¹³⁴

Some cases of MRSA actually may be caused by infection with *S. aureus* that lacks the *mecA* gene responsible for true methicillin resistance. The mechanism of resistance in these cases may be hyperproduction of β -lactamase.¹⁵⁴ Frequently in these cases, methicillin resistance is borderline, with minimal inhibitory concentrations (MICs) of 8 μ g/mL or less. The clinical significance of these isolates is unknown.

Management of Methicillin-Resistant *Staphylococcus aureus*

MRSA first was described within 1 year of the introduction of penicillinase-resistant penicillins.¹⁴⁶ Initial reports of infection appeared in England in the early 1960s and subsequently were followed by reports from other European countries.^{177,302} In the United States, only sporadic cases were observed initially^{167,177} and not until 1968 was the first nosocomial outbreak described.²² Since then, the prevalence of MRSA in the hospital setting has increased steadily. In a survey of US hospitals performed in 1989, 97% reported the presence of MRSA.³¹ The SCOPE prospective surveillance project conducted between 1995 and 2001 identified more than 3400 episodes of nosocomial bacteremias in children. *S. aureus* accounted for 9% of isolates.³³⁹ The proportion of *S. aureus* isolates that were MRSA increased from 10% in 1995 to 29% in 2001. Risk factors associated with infection or colonization with MRSA include recent or prolonged hospitalization, exposure to antibiotics, and stay in an intensive care unit.¹⁹⁷ Nosocomially acquired MRSA appears to be fully virulent, with in vitro characteristics similar to those of methicillin-susceptible staphylococci,

and equivalent virulence in studies of experimental infection in mice. Clinical studies confirm comparable mortality rates.^{132,315} These strains characteristically are multiresistant and usually show no, little, or decreased susceptibility to the standard cephalosporins, aminoglycosides, erythromycin, clindamycin, and tetracyclines.^{5,331}

Epidemic outbreaks of nosocomially acquired MRSA are not uncommon. In these outbreaks, nasopharyngeal colonization with MRSA often occurs before infection. A high rate of nasal and hand carriage has been observed in health care workers associated with units that have MRSA outbreaks.²³³ The usual approach to outbreaks has been to emphasize hand washing between examining and caring for patients. Strict isolation in a private room generally is advocated.²³⁴ Single-room isolation may be impractical in neonatal and some pediatric intensive care units, where isolation facilities are in short supply and a single MRSA-colonized patient may occupy a room for months. Strict adherence to universal precautions (body substance isolation) with all moist body fluids and strict hand washing between seeing patients appear to be rational alternatives to “strict isolation.”²⁰⁵ Intranasal application of mupirocin ointment has been found to be capable of eliminating nasal and hand carriage of both colonized patients and hospital staff.²⁷⁰ Interventions to control outbreaks of MRSA in intensive care or other units are multifaceted, and the reader is referred to major guidelines for recommendations.^{234,292}

Occasional cases of MRSA infection apparently acquired in the community were observed sporadically in the 1970s. However, these infections were from patients who were chronically ill, and many gave a history of nursing home residence, recent admission to acute or chronic health care facilities, previous receipt of antibiotics, or intravenous drug abuse.^{185,218,280,306} Hence, in these cases, infections usually were traceable to the hospital setting. By contrast, since the 1980s, cases of true CA-MRSA infection in patients without identified risk factors have appeared in the literature. The first reports in children arose from small MRSA outbreak investigations.¹²³ Subsequently Rathore and Kline described three patients with deep-seated infections caused by MRSA acquired in the community.²⁶⁹ In the 1990s, reports of CA-MRSA in patients without known risk factors continued to appear sporadically in the literature. However, most of the infections described occurred in adults.^{115,180,231} Four pediatric deaths in Minnesota and North Dakota in the period 1997 to 1999 demonstrated the potential for severe disease from CA-MRSA infections.¹² The landmark study describing the changing epidemiology of CA-MRSA in children was published in 1998.¹³¹ Herold and colleagues performed a retrospective review of medical records and compared the frequency of *S. aureus* isolation in hospitalized children during two time periods: between 1988 and 1990 and between 1993 and 1995. The prevalence of CA-MRSA in children without identified risk factors was 25.9 times higher in 1993 to 1995 than in 1988 to 1990.¹³¹ After the publication of this article, several reports of CA-MRSA in children without risk factors from different parts of the United States and many regions of the world have appeared.^{40,50,155,162,263,283,345} This explosive increase in reporting that occurred in just a few years suggests that clones of CA-MRSA have unique properties that allow rapid spread once they are introduced into the community.¹⁵⁸

All reports of the clinical characteristics of CA-MRSA infection in children without risk factors document a predominance of superficial infections, including subcutaneous abscesses and cellulitis.^{65,162} However, a large proportion of children with abscesses require admission to the hospital for incision and drainage under anesthesia.¹⁶² Recurrent skin infections are also very common.^{7,29} Invasive disease with CA-MRSA, including severe, life-threatening infection, osteomyelitis, septic arthritis, and pneumonia, accounted for about 5% of cases in children seeking care in an emergency center of a large children's hospital in Houston.^{111,112,162} As previously noted, the CDC ABC surveillance study noted an increasing incidence of invasive community-associated MRSA infections over the years 2005 to 2010 in children in the United States.¹⁴³ In another study using nationwide administrative data, the incidence of MRSA-coded osteoarticular infections increased from 0.02 per 1000 admissions in 1997 to 0.36 per 1000 admissions in 2012.³⁰³

Unlike hospital-acquired MRSA, CA-MRSA isolates usually are susceptible to most non- β -lactam antibiotics, including clindamycin,

FIG. 80.5 D test.

gentamicin, trimethoprim-sulfamethoxazole, and doxycycline or minocycline, in addition to vancomycin, daptomycin, and linezolid.¹⁵⁷ Erythromycin susceptibility is somewhat more variable, with the proportion of susceptible isolates varying from 29% to 80% in various studies.^{116,131,141,235} Macrolide (erythromycin, azithromycin, clarithromycin)-resistant strains remain susceptible to clindamycin if the macrolide resistance is caused by an efflux pump (MEF). Clindamycin, lincosamide, and streptogramin B resistance can be constitutive (MLS_B) or inducible (iMLS_B). Both mechanisms can be detected with molecular methods and can also be detected reliably in the routine laboratory by the “D test” (Fig. 80.5).⁸⁵ The D test detects the presence of inducible MLS_B resistance by the disk approximation method. Clindamycin- and erythromycin-impregnated disks are set 15 to 20 mm apart over Mueller-Hinton agar containing a standard inoculum of bacteria. After a 24-hour incubation period, if the zone of inhibition around the clindamycin disk is flattened or blunted (“D shaped”) on the side facing the erythromycin disk, the isolate is classified as having an inducible MLS_B resistance phenotype.¹⁸¹ Alternative approaches include a single-well microdilution test containing both clindamycin and erythromycin and automated methods.¹⁴⁴

Inducible macrolide-lincosamide-streptogramin B (MLS_B) resistance consists of modification of the target rRNA of *S. aureus* mediated by the presence of the resistance-conferring *erm* (erythromycin resistance methylase) gene, which encodes a 23S rRNA methylase.^{145,181} In vitro and in vivo evidence indicates that, in the presence of erythromycin resistance, *S. aureus* could become resistant to clindamycin during therapy with this antibiotic.^{74,217,247,330} Although 14-membered ring macrolides such as erythromycin are the most potent inducers, lincosamides such as clindamycin also can act as weaker inducers.¹⁸¹ This ability may have clinical relevance in the setting of infections for which the bacteria are not eliminated quickly and may be exposed to subinhibitory concentrations of clindamycin for any amount of time. Examples include therapy for undrained deep-seated abscesses or treatment of osteoarticular infections. In patients infected with a strain having the inducible MLS_B resistance genotype and expressing the erythromycin-resistant, clindamycin-susceptible phenotype, cases of clindamycin therapeutic failure have been reported.^{96,186,291} Vancomycin is the drug of choice for serious MRSA infections. There is no evidence that addition of an aminoglycoside or rifampin to vancomycin is beneficial for treatment of infections that do not involve prosthetic material.²⁵⁰ Linezolid, an oxazolidinone antibiotic, has demonstrated significant activity against

MRSA, vancomycin-resistant enterococci, and penicillin-resistant *Streptococcus pneumoniae*. Linezolid is an important option for treatment of MRSA infections due to clindamycin-resistant isolates and may be a drug of choice for treating MRSA pneumonia.^{160,341} It is available in both oral and intravenous formulations. Quinupristin-dalfopristin is an intravenous streptogramin antibiotic combination that has been found to be effective in the treatment of MRSA and vancomycin-resistant *Enterococcus faecium* infections in patients intolerant of or failing previous therapy. The frequent development of phlebitis with parenteral administration through a peripheral vein mandates the use of central venous access whenever possible. Both linezolid and quinupristin-dalfopristin are expensive, so their use should be restricted to situations for which other alternatives are not feasible. Quinupristin-dalfopristin has only been studied in children in compassionate use trials, and the development of other agents has limited its use in pediatrics.²⁰⁰ Daptomycin has rapidly bactericidal activity in vitro against MRSA and is an effective agent for treating MRSA infections, including bacteremia and right-sided endocarditis in adults.^{34,94} Pharmacokinetic studies in infants and older children indicate a larger dose per kilogram is required to obtain the same drug exposure in adults that resulted in effective treatment of MRSA infections.^{1,35} The safety and efficacy of daptomycin for treating *S. aureus* infections in children are being studied but to date appears to be safe and effective in the treatment of serious gram-positive infections in children.³⁰⁸ Ceftaroline is a fifth-generation cephalosporin that is approved for treatment of MRSA skin and soft tissue infections in adults, and studies are being conducted to determine the pharmacokinetics, safety, and efficacy of this agent in children.²⁸² Case reports suggest that daptomycin or ceftaroline provides a safe and effective option for the treatment of invasive MRSA infections in children.^{25,336}

For severe infections caused by MRSA, the antibiotic of choice is vancomycin. In areas where CA-MRSA has been isolated from children without identified risk factors, severe, life-threatening infections suspected to be caused by *S. aureus* should be treated empirically with both nafcillin and vancomycin because nafcillin is a more active antibiotic than is vancomycin for the treatment of methicillin-susceptible isolates.¹¹⁴ Antibiotic therapy can be adjusted subsequently after antibiotic susceptibility testing results are available. Clindamycin and linezolid are options for therapy depending on the susceptibility of the isolate, the desired route of administration, and the absence of endovascular involvement. Daptomycin is approved for serious *S. aureus* infections including bacteremia in adults but is not yet approved for children.^{13,94} Tigecycline is another agent most useful for polymicrobial infections including MRSA in adults but has not been studied in children.³⁰⁰ The role of parenteral trimethoprim-sulfamethoxazole in treating invasive MRSA infections is unclear owing to the paucity of reports.²²³

For mild to moderate skin and soft tissue infections caused by CA-MRSA, empirical treatment may include other antibiotics such as clindamycin or trimethoprim-sulfamethoxazole. Doxycycline and minocycline are options for children older than 8 years.²⁷⁵ If more than 90% or so of community *S. aureus* isolates are susceptible to clindamycin, clindamycin can be used for empirical treatment of moderately invasive infections, such as in children with osteomyelitis or pneumonia and empyema who do not require intensive care and in whom bacteremia is not thought to be likely. This approach is not recommended when the clindamycin rate exceeds 10% of the CA-MRSA and CA-MSSA isolates combined.⁶⁴ Vancomycin or linezolid would be considerations in such circumstances.¹⁶⁰ Once an organism is isolated, therapy is modified based on susceptibility patterns. For moderate MSSA infections, nafcillin, oxacillin, and cefazolin are the preferred parenteral agents, and dicloxacillin and cephalixin are the preferred oral agents.

The origin of CA-MRSA is not known. The absence of health care exposure in patients harboring the bacterium, the unique antibiotic susceptibility characteristics of these isolates, and distinctive pulsed-field electrophoresis patterns that are different from the patterns of hospital-acquired MRSA isolates for a given institution suggest that the origin may be the community and that these isolates were not merely transferred from the hospital setting.^{3,117} The unique combination of the gene complex and the much smaller *SCCmec* size than identified in the *SCCmec* of hospital-acquired MRSA also suggests a different origin.²⁰⁶ Whether the origin is the hospital or the community, the changing epidemiology of

MRSA is remarkably similar to the emergence of penicillin-resistant *S. aureus* that occurred in the 1940s and 1950s.⁴⁷ Finally the increasing rate of isolation of MRSA will mandate the use of alternative antibiotics, which in turn may promote the development of additional resistance to other antibiotic classes, the one of most concern being resistance to glycopeptide antibiotics such as vancomycin. Although vancomycin is the antibiotic of choice for severe MRSA infection, its use must remain monitored and controlled because clinical isolates with decreased susceptibility to this antibiotic—vancomycin- or glycopeptide-intermediate *S. aureus* (VISA or GISA)—have been reported.²⁹⁴

In June 2002, the first documented infection by vancomycin-resistant *S. aureus* in the United States was reported.⁴⁵ The isolate, obtained from a catheter exit site of a 40-year-old diabetic patient undergoing chronic dialysis, had high MICs for vancomycin (1024 µg/mL) and oxacillin (>16 µg/mL) but was susceptible to chloramphenicol, linezolid, minocycline, quinupristin-dalfopristin, and trimethoprim-sulfamethoxazole.^{45,48} Since then, 14 total isolates have been reported from Michigan, Pennsylvania, Delaware, and New York.^{46,188,313,314,329} All of the vancomycin-resistant *S. aureus* strains are resistant to the glycopeptides by virtue of the *vanA* gene found in the enterococci. VISA strains (MIC of 4 or 8 µg/mL) do not harbor the *vanA* gene and are intermediately resistant to vancomycin because of a thickened cell wall containing vancomycin-binding dipeptides.^{61,124,135} Vancomycin (and other glycopeptides)-intermediate resistance is not detected by disk diffusion techniques and may not be consistently detected by automated systems.³¹² In response to Clinical and Laboratory Standards Institute (CLSI) guidelines, microbiology laboratories have lowered the breakpoints for vancomycin susceptibility to 2 µg/mL or less, for intermediate resistance to 4 to 8 µg/mL, and for resistance to 16 µg/mL or more. In actuality, very few *S. aureus* have MICs greater than 4 µg/mL.³¹³

Several studies in adults have reported worse outcomes for vancomycin treatment of MRSA infections, especially bacteremia or ventilator-associated pneumonia, when isolates have a vancomycin MIC greater than 1.0 µg/mL.^{125,198,279} The relative increase in vancomycin MIC has been referred to as “vancomycin creep,” but the MIC values are dependent on the method used to determine the MIC.¹⁵³ MIC results generally are higher using the E-test, but outcome of treatment may correlate better with E-test results compared with other methods.¹⁷⁴ As a result, dosing vancomycin such that the trough concentration remains between 15 and 20 µg/mL to achieve optimal drug exposure is recommended by experts for adults with serious MRSA infection.^{194,277} However, “vancomycin creep” does not appear to be a problem in MRSA isolates recovered from children, and higher vancomycin troughs are associated with nephrotoxicity, and thus the need to target vancomycin trough levels at 15 to 20 µg/mL is unclear in children.^{101,147,199,213,346} In fact, McNeil et al. found that over the years 2003 to 2013, vancomycin MICs for *S. aureus* isolates recovered from children with health care-associated bacteremia at Texas Children’s Hospital had shifted to fewer isolates with MIC of 2 µg/mL or more over the study years.²²¹ This group also reported that the outcomes of patients whose vancomycin troughs were greater than 15 µg/mL compared to those with troughs of less than 15 µg/mL were similar. However, those with higher troughs had more nephrotoxicity. Furthermore doses of vancomycin much higher than the conventional dose (60 mg/kg per day) are often required in children to achieve this trough target. One approach would be to target this trough value for treatment of serious infections in selected patients when initiating vancomycin but to reduce the dose to 60 mg/kg per day once the patient has clearly improved clinically and blood cultures are negative. Daptomycin and ceftaroline will likely become primary option for treating serious invasive infections in children caused by MRSA strains with reduced susceptibility to vancomycin after the optimal doses and safety profiles of these agents have been established in children.

PREVENTION

Staphylococcal infections are so common that virtually everyone has had at least some minor encounters. Skin infections occur more commonly in tropical climates or during warm, humid weather in temperate areas and are likely to arise in moist areas of the body such as the axillae, perineal region, and skin creases. High standards of personal hygiene,

careful cleaning, and adequate protection of abrasions and minor lacerations reduce the likelihood of a skin infection developing.³⁰⁹ Early attention to minor infection in these small wounds with careful cleaning and antibiotic ointment may help prevent more serious or invasive infection. Even minor cutaneous infections can precede the development of more serious staphylococcal infections such as osteomyelitis, pneumonia, and endocarditis.

Person-to-person spread from an overt lesion is a major route for dissemination of infection within families, in hospitals, and in schools. A person with an infected, purulent wound should receive prompt treatment and be excused from school and from such occupations as hospital worker or food handler while the infection is open or draining. At home, special precautions should be taken in care and dressing of the wound. Disposable gauze pads should be used to wash and dry it, and towels and washcloths should not be shared with other members of the family. For children with recurrent infections or for families with multiple family members with infection, in addition to routine hygienic measures, Fritz and associates⁹⁸ found that a 5-day regimen of twice-daily intranasal mupirocin and daily chlorhexidine body washes for everyone in the household reduced the frequency of subsequent skin and soft tissue infections in the child as well as other household members. The Infectious Diseases Society of America guidelines also include mupirocin along with chlorhexidine as part of a strategy to decolonize patients with recurrent skin and soft tissue infections.¹⁹⁴ Resistance to mupirocin or chlorhexidine is likely to increase as these agents are used more frequently in the community for prevention programs.^{183,220} Thus monitoring for resistance to mupirocin and chlorhexidine among *S. aureus* isolates should be more routinely performed. Dilute bleach kills *S. aureus* in vitro very quickly and has been used by dermatologists for years as part of a strategy to prevent staphylococcal skin infections.^{86,159} We have found that, along with education regarding routine hygienic measures, having the patients take a bath for 15 minutes twice a week in water to which bleach (1 teaspoon/gallon of bath water) has been added may be somewhat helpful.¹⁶¹

To date no vaccine targeting polysaccharide, adhesion proteins, or other components of *S. aureus* has been successfully developed for the prevention of *S. aureus* infections.^{63,93,258,259} One trial using immune globulin enriched for antibody to clumping factor A failed at preventing staphylococcal infections in low-birth-weight infants,²⁸ and a monoclonal antibody directed against clumping factor A was investigated preliminarily in adults with *S. aureus* bacteremia.³³³ A polyclonal IgG preparation containing high levels of antibody to *S. aureus* capsular polysaccharides 5 and 8 has been developed by collecting plasma from healthy donors immunized with StaphVAX.²³ The pharmacokinetics and safety of this product in very-low-birth-weight infants were established in a phase 2 trial, but further development of this antibody preparation is questionable. The safety and pharmacokinetics of human chimeric monoclonal antibody directed against the lipoteichoic acid, an integral component of the cell wall of gram-positive organisms, including *S. aureus*, has been evaluated in a phase 2 study in very-low-birth-weight infants.²⁸ This antibody (pagibaximab) also did not appear to be efficacious in preventing invasive *S. aureus* infections in very-low-birth-weight infants.

Perhaps taking advantage of the *S. aureus* genome with a reverse vaccinology approach will lead to a safe and efficacious vaccine.³⁰⁵ But, until such time, simple measures such as frequent hand washing, attention to skin breaks, and avoiding contact of obviously infected skin lesions are the approaches for preventing common *S. aureus* infections.

Coagulase-Negative Staphylococcal Infections

81

David Y. Hyun

Coagulase-negative staphylococci are some of the most common pathogens of healthcare-associated infections. Neonates, immunocompromised patients, and patients with indwelling medical devices are at higher risk for acquiring coagulase-negative staphylococcal infections.^{180,199,227,276} Coagulase-negative staphylococci are the most frequently isolated organisms in the microbiology laboratory, in part owing to their commensal nature with human skin and mucosal membranes. Diagnostic challenges remain despite advances in molecular epidemiologic tools, owing to the difficulty of accurately differentiating true infections from contaminated clinical samples. Effective therapy can be difficult to achieve because of the high prevalence of resistance to multiple antibiotics. The discussion presented here is focused on the microbiology, epidemiology, pathogenesis, clinical manifestations, diagnoses, and treatment of infections caused by these ubiquitous organisms.

HISTORICAL BACKGROUND

Frederick Julius Rosenbach is credited with identifying *Staphylococcus epidermidis* in 1884, which at the time he named *S. albus* to denote the white colonies and to differentiate it from *S. aureus*, which was observed to have yellow colonies. The *S. albus* term was subsequently used as the descriptive terminology for all coagulase-negative staphylococci until the 1960s when coagulase-negative staphylococci began gaining recognition as significant infectious pathogens in certain patient populations. They were identified as etiologic agents of infections in neonates with sepsis and in adult patients with atrioventricular shunts and peritoneal catheters.^{33,35,149,243} As a result, efforts to further differentiate and delineate species of coagulase-negative staphylococci led to the new nomenclature of *S. epidermidis* as well as to the identification and recognition of *S. saprophyticus* as a pathogen of the urinary tract. Descriptions and identifications of other species followed. Today there are more than 40 known species of coagulase-negative staphylococci.

MICROBIOLOGY

Staphylococci are gram-positive, nonmotile, non-spore forming, and catalase-positive bacteria. They are members of the family Micrococcaceae along with *Micrococcus*, *Planococcus*, and *Stomatococcus*. Members of the genus *Staphylococcus* have a low DNA G + C content (30 to 39 mol%), whereas members of the genus *Micrococcus* have a G + C content within the range of 66 to 75 mol%.¹³⁵ Staphylococci grow in irregular clusters, which are often described to resemble grapes when viewed microscopically. The cell wall is composed primarily of peptidoglycan with teichoic

acid and an assortment of interspersed proteins, many of which are exposed on the surface and interact with host cells.²⁰¹ The teichoic acid has a glycerol backbone, in contrast to the ribitol of *S. aureus*.¹⁸⁸ Staphylococci are further divided by their ability to produce coagulase, the enzyme responsible for coagulation of rabbit plasma. *S. aureus* and *S. hyicus-intermedius* group constitute the coagulase-positive species. Most clinical laboratories utilize an alternative agglutination method that targets antigens specific to *S. aureus* to differentiate it from coagulase-negative staphylococci.¹¹³ Fermentation of mannitol is another feature of *S. aureus* that differentiates it from most coagulase-negative staphylococci.

Species identification for coagulase-negative staphylococci requires assessment of a combination of features, including colony morphology, oxygen requirements, novobiocin resistance, aerobic acid production from carbohydrates, and selected liability to enzymatic activities.^{133,136} Resistance to novobiocin is observed in several species including *S. saprophyticus*.²⁰⁸ Commercial kits utilizing rapid biochemical reactions are available to identify species of coagulase-negative staphylococci. Although these kits have varying degrees of confidence and accuracy depending on the species, most systems can reliably identify species frequently associated with human disease, such as *S. epidermidis*, *S. haemolyticus*, and *S. saprophyticus*.²¹¹ *S. lugdunensis*, which has recently emerged as a significant pathogen in humans, can be differentiated from other coagulase-negative staphylococci by a negative tube coagulase test, a positive pyrrolidonyl arylamidase (PYR) reaction, and positive ornithine decarboxylase activity.⁷⁶

Matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) uses mass spectroscopy for bacterial identification from clinical samples and has been demonstrated to be a rapid and accurate diagnostic tool for coagulase negative staphylococci.^{9,65,155} By reducing the time to identification and speciation for coagulase negative staphylococci, MALDI-TOF can assist clinicians in making timely antibiotic treatment decisions.¹⁸¹

EPIDEMIOLOGY

Coagulase-negative staphylococci are primarily isolated from human skin and mucosal membranes (Table 81.1). The number of commensal coagulase-negative staphylococci on skin can vary from 10 to 10⁶ colony-forming units per square centimeter depending on the anatomic location, with some species demonstrating a predilection for colonizing specific body sites.¹³⁴ Colonization can begin as early as the neonatal period. Two studies addressed the colonization of *S. epidermidis* in

TABLE 81.1 Coagulase-Negative Staphylococci Commensal to Human Skin and Mucosal Membranes

Species	Anatomic Site	Pathogenic Potential
<i>S. epidermidis</i>	Nares, axillae, skin	Common
<i>S. saprophyticus</i>	Occasionally skin	Common
<i>S. haemolyticus</i>	Skin of head, arms, and legs	Uncommon
<i>S. hominis</i>	Axillae, skin of head, arms, and legs	Uncommon
<i>S. lugdunensis</i>	Widely distributed on body	Uncommon
<i>S. simulans</i>	Occasionally skin	Uncommon
<i>S. cohnii</i>	Occasionally skin	Uncommon
<i>S. warneri</i>	Occasionally skin	Uncommon
<i>S. saccharolyticus</i>	Rarely skin	Rare
<i>S. caprae</i>	Occasionally skin	Rare
<i>S. capitis</i>	Skin of head, face, ears, and arms	Rare
<i>S. auricularis</i>	Ears	Rare
<i>S. schleiferi</i>	Skin	Rare
<i>S. xylosus</i>	Occasionally skin	Rare

low-birth-weight neonates,^{50,99} with both reports describing rapid colonization where 75% of neonates were colonized by 2 weeks of age. Although most infants acquire coagulase-negative staphylococci from environmental sources, including hospital personnel, a few are colonized by vertical transmission.^{25,98,202}

Staphylococcus epidermidis continues to be the predominant species identified among commensal and clinical isolates.²⁸⁴ Most coagulase-negative staphylococci cause nosocomial infections frequently associated with indwelling prosthetic devices such as central venous catheters. As a result, the increase in use of these medical devices has led to a proportional increase in the rates of infections.²²⁷ *S. saprophyticus* and *S. lugdunensis* are notable exceptions that have been associated with community-acquired urinary tract infections and native-valve endocarditis, respectively.^{13,147}

Epidemiologic typing methods are used in coagulase-negative staphylococcal infections when investigating a common-source outbreak or repeated infections within an individual (Table 81.2).^{187,211,276} Older phenotypic typing tools such as antibiotic susceptibility pattern analysis, biochemical reactivity, slime production detection, and serologic typing lacked the power to differentiate closely related strains and were hampered by poor sensitivities and specificities.^{255,284} In contrast, molecular genotyping methods have demonstrated higher discriminatory power with pulse-field gel electrophoresis (PFGE) becoming the method of choice when investigating patterns of transmission and sources of outbreaks.^{29,145,175,263,276} Random amplification of polymorphic DNA (RAPD) by polymerase chain reaction (PCR) also has been successful

FIG. 81.1 Scanning electron microscopy of slime-producing coagulase-negative staphylococci. (From Peters G, Locci R, Pulverer G. Adherence and growth of coagulase-negative staphylococci on surfaces of intravenous catheters. *J Infect Dis.* 1982;146:479–482.)

in identifying clonal outbreaks and transmissions. Although it is less discriminatory than PFGE, RAPD is less costly and time consuming.^{26,218} Multilocus sequence typing (MLST) can be used to delineate clonal relationships between strains and has been used to identify predominant clones from a group of clinical isolates.^{159,292}

PATHOGENESIS

Risk factors for coagulase-negative staphylococcal infection are associated with nosocomial interventions that modify or bypass the host defense and immune mechanisms. They include immunosuppression,^{72,127} prior antibiotic therapies,^{128,245} and breakdown of mucocutaneous barriers, which is most commonly seen with the presence of prosthetic devices such as central venous catheters, cerebrospinal fluid (CSF) shunts, and peritoneal dialysis catheters.^{14,21,67,152}

Biofilms (Fig. 81.1) are major virulence factors for coagulase-negative staphylococci especially in infections associated with prosthetic devices.^{5,43,45,57–59,63,159,266,274} They are agglomerates of bacteria embedded in extracellular material and provide a mechanism of evasion against host defense and antibiotic activities.^{68,89,120,140,247,248,275,279,280} They act as mechanical barriers to most immune cells, interfere with phagocytic activity, and limit antibiotic diffusion. Biofilm formation occurs in steps, with initial attachment followed by accumulation and detachment.

The initial attachment of *S. epidermidis* to polystyrene and other surfaces^{160,159} is primarily mediated by several microbial surface components recognizing adhesive matrix molecules (MSCRAMMs).^{109,114,228,265,279} MSCRAMMs facilitate binding to specific human matrix proteins, including fibrinogen, fibronectin, vitronectin, and collagen. Nonspecific electrostatic and hydrophobic interactions^{106,111,267} and teichoic acids¹¹⁴ also play roles in adhesion. Initial adhesion is followed by intercellular aggregation and accumulation of biofilms mediated by production of polysaccharide intercellular adhesion (PIA),^{108,229} which acts as the primary component for the extracellular matrix of *S. epidermidis*. In addition to its role in biofilm formation, PIA also acts as a hemagglutinin^{159,226} and provides protection against phagocytosis and killing by human polymorphonuclear leukocytes.^{249,280} The *ica* operon encodes enzymes necessary for PIA production.¹⁰⁸

In numerous epidemiologic studies, the presence of the *ica* operon has been associated more frequently with *S. epidermidis* strains isolated from hospitalized patients with prosthetic device infections than with community strains isolated from healthy individuals. Eighty-one to 89% of isolates from hospitalized patients have been reported to carry the *ica* operon. In contrast, only 6% to 38% of community-acquired isolates were found to carry the *ica* operon.^{77,138,268} However, utilizing

ica operon detection to differentiate between invasive and commensal strains of *S. epidermidis* has proven to be unreliable. Investigations of clinical strains obtained from patients in neonatal intensive care units, bone marrow transplant units, and oncology units have shown that although both invasive and commensal strains demonstrated high carriage rates of the *ica* operon, no significant difference was found between the two groups.^{30,55,205,222} Higher proportions of invasive strains demonstrated biofilm production in quantitative assays compared with commensal strains.^{30,222} Most of the commensal strains were biofilm-negative despite possessing the *ica* operon, a finding suggesting that regulation of gene expression plays a large role in virulence. Clinical strains of *S. epidermidis* producing biofilms independently of PIA have also been described.^{137,222,221}

Unlike *S. aureus*, which is capable of producing various cytolytic and superantigenic toxins, *S. epidermidis* produces very few toxins.²⁷⁸ More recently, phenol-soluble modulins (PSMs) have been identified and characterized as a family of peptides produced by *S. epidermidis* with cytolytic and proinflammatory capacities.^{41,170} Delta toxin is part of the PSM complex and is an enteropathogenic toxin encoded by the *hld* component of the regulatory system *agr* that has been linked to necrotizing enterocolitis in infants.²⁴¹ *S. epidermidis* also produces antibacterial peptides called *lantibiotics* that may play a role in bacterial interference on skin and mucous membranes and in the creation of an ecologic niche for *S. epidermidis*.¹⁴² Numerous extracellular enzymes are also produced by coagulase-negative staphylococci; an extracellular metalloprotease with elastase activity; a cysteine protease that degrades human secretory immunoglobulin A, immunoglobulin M, serum albumin, fibrinogen, and fibronectin; and an extracellular serine protease involved in epidermin processing.^{107,278,282} Two lipases have been postulated to facilitate skin colonization.^{107,278}

S. saprophyticus can cause urinary tract infections in the absence of indwelling catheters.¹⁴² Several virulence factors have been described to explain its pathogenic potential to adhere and persistently grow in the urinary tract. A surface-exposed protein with hemagglutinin and adhesive properties⁸⁴ and a surface fibrillar protein,⁸³ designated *ssp*, are associated with attachment to urinary tract epithelium. Urease production also has been associated with invasiveness of this organism by causing damage to bladder tissues.^{81,82} The whole genome of *S. saprophyticus* has been sequenced and compared with *S. aureus* and *S. epidermidis*.¹⁴² Analysis revealed a single, unique cell wall-anchored protein with properties of hemagglutination and adherence to human bladder cells. A high population of ionic transport systems capable of providing osmotolerance in the highly variant ionic environment of urine also was demonstrated.

S. lugdunensis has emerged as a significant pathogen associated with more severe and aggressive forms of endocarditis compared to other coagulase-negative staphylococcal species. This may be explained by the ability of *S. lugdunensis* to directly bind to von Willebrand factor, thus facilitating adhesion to vessel walls and cardiac valves while allowing the organism to withstand shear forces.¹⁵⁴

CLINICAL MANIFESTATIONS

Coagulase-negative staphylococci have been implicated in a variety of clinical infections, which are mostly nosocomial in immunocompetent and immunocompromised patients (Box 81.1).^{133,199,230} Because of the commensal nature of these organisms, separating true infections from contaminated culture results continues to be a challenge. This is further complicated by the variability among clinical studies when defining the criteria for clinically significant cultures.⁶¹ Repeated isolation of the same phenotypic or genotypic strains of coagulase-negative staphylococci can facilitate interpretation. Quantitative cultures can also add value in the diagnosis of catheter-associated bacteremia by demonstrating a five- to tenfold increase in the number of colony-forming units in cultures obtained from a catheter compared with cultures from a peripheral blood vessel. The Committee on Infectious Diseases of the American Academy of Pediatrics suggested the following considerations to distinguish pathogenic coagulase-negative staphylococci from contaminants: (1) two or more positive blood cultures from different collection sites, (2) a positive culture from blood and another usually

BOX 81.1 Clinically Significant Coagulase-Negative Staphylococcal Infections

- Bacteremia:
 - Neonates
 - Patients with leukemia and lymphoma
 - Bone marrow transplant recipients
- Infections in patients with medical devices:
 - Intravascular catheters
 - Cerebrospinal fluid shunts
 - Peritoneal dialysis catheter
 - Prosthetic valves
- Other infections:
 - Prosthetic joints
 - Vascular grafts and prostheses
 - Hemodialysis catheter
 - Pacemaker
 - Scalp electrodes
- Native valve endocarditis
- Urinary tract infections
- Miscellaneous infections:
 - Endophthalmitis
 - Postoperative wound infections
 - Osteomyelitis
 - Toxic shock syndrome

sterile site with identical antimicrobial susceptibility patterns, (3) growth in continuously monitored blood culture system within 15 hours of incubation, (4) clinical findings of infection, (5) an intravascular catheter that has been in place for 3 days or more, and (6) similar or identical genotypes among all isolates.⁴

Clinical presentation markedly differs from that of *S. aureus* infection. In general, infections caused by coagulase-negative staphylococci are more indolent and can have a subacute or even chronic course. They occur mostly as health care-associated bacteremia and infections of prosthetic medical devices.

Bacteremia

Coagulase-negative staphylococci, particularly *S. epidermidis*, are the most common pathogens in nosocomial bloodstream infections and have become the major nosocomial pathogens in most studies.^{61,220} A large surveillance study between 1995 and 2001 among 49 hospitals in the United States showed that coagulase-negative staphylococci were identified in 43% of nosocomial bacteremias in pediatric patients.²⁸⁵ In another single center study, analysis of 4405 episodes of bloodstream infections from a children's hospital during 2002 to 2012 demonstrated that coagulase-negative staphylococci were identified in 49% of these cases.¹⁴⁶ Among oncologic immunocompromised pediatric patients, coagulase-negative staphylococci accounted for up to 35% of all positive blood culture isolates.^{2,12,144} A significant majority of all coagulase-negative bacteremia occurs with the use of indwelling vascular catheters.

Neonatal Bacteremia

Coagulase-negative staphylococci are the most frequent cause of late-onset septicemia and bloodstream infections among premature infants.^{18,73,90,100,97,186,200} These infections are found predominantly in premature infants with a gestational age of less than 34 weeks and those with low birth weights,^{90,104,118,200} owing to their higher likelihood of prolonged use of a central catheter and parenteral nutrition and their immature immune system, including quantitative and qualitative neutrophil deficiencies.^{37,244,285} The presence of indwelling peripheral or umbilical catheters has been implicated in approximately half of neonatal coagulase-negative staphylococcal bacteremias.^{18,97,185,195} The salient features from six large studies are listed in Table 81.3.^{73,97,123,124,178,200}

^a1981–86.

^b1987–94.

Clinical findings of coagulase-negative staphylococcal bacteremia are mostly indolent and subtle and include bradycardia, apnea, and temperature instability (see Table 81.3). The frequency of fulminant late-onset sepsis caused by coagulase-negative staphylococcal bacteremia is very low (1%).¹²⁶ Mortality rates associated with coagulase-negative staphylococcal infections in neonates are much lower compared with those with other pathogens.^{161,258} However, neonates with prolonged and persistent bacteremia have higher mortality rates that are comparable to those of other pathogens.^{39,118} In addition, polymicrobial bloodstream infections that include coagulase-negative staphylococci as one of the pathogens are likely to have higher mortality rates.¹⁹²

Laboratory studies need to be interpreted within clinical contexts and risk factors consistent with coagulase-negative staphylococcal bacteremia.^{104,112,166,182} Leukocytosis may not be present, and there have been conflicting findings in regard to the utility of biofilm detection as a marker for infection.^{97,200} Use of quantitative blood cultures correlated with clinical criteria may have a role in identifying the true pathogen.²⁵⁷ The Centers for Disease Control and Prevention (CDC) defines laboratory-confirmed bloodstream infections for common skin contaminants including coagulase-negative staphylococci in patients 1 year or younger as (1) at least one finding of fever, hypothermia, apnea, or bradycardia; (2) signs, symptoms, and laboratory findings not consistent with infection at another site; and (3) isolation of an organism from two or more blood cultures drawn on separate occasions.¹¹²

Persistence of coagulase-negative staphylococcal bacteremia despite administration of adequate antibiotic therapy has been described in neonates.^{60,131,200} Mean duration of persistent bacteremia is 10 to 14 days. This persistence was observed in patients with and without central venous catheters and in patients with normal findings on cardiac echocardiography. Neonates with persistent bacteremia had a significantly higher incidence of severe thrombocytopenia requiring platelet transfusions than did those with nonpersistent bacteremia.^{60,131}

Rarely coagulase-negative staphylococcal meningitis in the absence of intraventricular devices has been reported in low-birth-weight neonates with normal CSF white blood cell counts.⁹⁵ CSF examination may be considered in neonates with coagulase-negative staphylococcal bacteremia because abnormal CSF findings or a positive CSF culture may influence the duration of therapy. Coagulase-negative staphylococci also have

been implicated as etiologic agents of necrotizing enterocolitis,^{94,241} although one report showed no association.²²⁵

Bacteremia in Immunocompromised Patients

Immunocompromised patients with leukemia or lymphoma are at risk for coagulase-negative staphylococcal bacteremia (Table 81.4).^{2,12,79,144,212,213,246} In several reports, coagulase-negative staphylococci were the isolates most commonly causing bacteremia in pediatric patients with cancer and accounted for 35% to 50% of all initial isolates.^{2,12,144,203} One-third of these patients did not have central venous catheters at the time of their bacteremia.⁷⁹ Risk factors for this patient population include indwelling catheters, malnutrition, and myelosuppression, especially neutropenia after chemotherapy. In addition to catheter-associated bloodstream infections, translocation of pathogens through inflamed mucosal surfaces secondary to chemotherapy, including the gastrointestinal tract, is a prominent mechanism of bacteremia. One study utilizing molecular epidemiologic tools, including RAPD and PFGE analysis of clinical isolates obtained from adult neutropenic oncology patients, showed that skin flora was the likely source for 75% of coagulase-negative staphylococcal catheter-associated infections.¹⁸⁷

Coagulase-negative staphylococci have become the primary pathogens for bacteremia among hematopoietic stem cell transplant recipients.^{34,173} These episodes occur most often during periods of agranulocytosis before marrow engraftment,³⁴ and they can be fatal.²⁰ Most bacteremic episodes are due to use of central venous catheters and broad-spectrum antibiotics. Coagulase-negative staphylococci is also a frequent pathogen for bloodstream infections in solid organ transplant recipients.²²

Significant morbidity from coagulase-negative staphylococcal bacteremia can be attributed to the organism's acquisition of multiple antibiotic resistance that requires the use of antimicrobial agents with a higher risk for toxicity, such as vancomycin or linezolid.^{79,127,144,157,158,214,238} Mortality rates have varied from 0% to 11%.^{79,144}

Indwelling Medical Devices

Intravascular Catheter-Related Infections

Coagulase-negative staphylococci are the most common pathogens for catheter-related infections.^{75,172,287} Risk for infections varies among the different types of catheters. Short-term central venous catheters (CVCs),

TABLE 81.4 Clinical Characteristics of Coagulase-Negative Staphylococcal Bacteremia in Pediatric Patients With Cancer

defined as those in place for fewer than 14 days, account for the majority of catheter-related infections. Peripherally inserted central catheters (PICCs) carry similar risks of infection to those of short-term CVCs when used in intensive care units.¹⁷² However, the frequency of catheter-related infections for PICCs used for outpatient parenteral therapies appears to be significantly lower.^{151,272} Long-term CVCs that are surgically implanted with a tunneled portion and a Dacron cuff just inside the skin exit site^{32,110} also have lower infection rates at 0.14 per 100 catheter-days,¹¹³ with the catheter hub being the major source of infection.²¹⁶ Finally totally implanted vascular devices with subcutaneous ports or reservoirs carry the lowest infection risk, with rates of 0 to 0.04 per 100 catheter-days.^{113,224} Infections at the catheter insertion sites also can lead to bacteremia or septic thrombophlebitis, with further complications caused by metastatic spread.²¹⁵ Overall infectious complications involving central venous catheters have a variable reported frequency of 2.7% to 47%,^{21,86,103,156,176,253,277} with coagulase-negative staphylococci identified as the pathogens in approximately half of these cases. The wide range of frequency is attributed to the intended use of the catheters, types of catheters, frequency of catheter access, characteristics of patients, and use of preventive strategies.¹⁷²

As with other coagulase-negative staphylococcal infections, *S. epidermidis* is the predominant species associated with catheter-related infections, accounting for approximately 70% of cases.^{21,103} This likely correlates to the high prevalence of the organisms colonizing the human skin.¹³⁴ Other implicated coagulase-negative staphylococcal species include *S. haemolyticus*, *S. warneri*, and *S. hominis*.¹⁰³

Establishing accurate diagnoses of catheter-related coagulase-negative staphylococcal infections remains a challenge owing to the difficulty of differentiating true infections from contaminated specimens and depends on the patient's clinical status and the isolation of identical strains from repeated cultures. In addition, it is important to distinguish catheter-related bacteremia from secondary bacteremia caused by infections at other sites. The use of quantitative blood cultures has shown that catheter-related bacteremia has a 5- to 10-fold difference in bacterial concentration in blood cultures drawn from the catheter when compared with the concentration in peripheral cultures.^{74,219} When a catheter is removed because of a suspected catheter-related infection, a semiquantitative culture of the distal 5 cm of the catheter is recommended.¹⁷² This can be accomplished by rolling the distal portion of the catheter on an agar plate. Growth of more than 15 colony-forming units is indicative of catheter colonization.¹⁶²

Duration of antimicrobial therapy for uncomplicated coagulase-negative staphylococcal catheter-related infections depends on whether the catheter is removed or retained.¹⁷² When the catheter is no longer needed, it should be removed and the patient should be given 5 to 7 days of antimicrobial therapy. If the catheter is retained, the duration of antimicrobial therapy should be 10 to 14 days and accompanied by antibiotic lock therapy. Therapy with retention of a catheter carries a higher risk for recurrence.²¹⁷ Complicated catheter-related infections, including those with tunnel infections, port abscesses, septic thrombosis, endocarditis, and osteomyelitis, are indications for catheter removal. *S. lugdunensis* infections should be treated more conservatively in a manner similar to *S. aureus* infections

owing to the higher virulence of this organism compared with other coagulase-negative staphylococci.

Central Nervous System Shunts

Coagulase-negative staphylococci are the predominant pathogens for infections of central nervous system shunts that are used to relieve hydrocephalus by diverting CSF.¹³⁰ They account for 60% to 75% of all bacterial causes of shunt infections.^{130,183,250} Ventriculoperitoneal shunts that divert CSF into the peritoneal cavity have primarily been used since the 1960s because of their lower rate of mechanical complications.^{130,179,189} Ventriculoatrial shunts that divert CSF into the right atrium are used infrequently because of higher complication rates.¹⁸⁹ However, the incidences of infection involving both ventriculoperitoneal and the ventriculoatrial shunts are comparable.^{130,189,250} Infection rates are higher in neonates.

Shunt infections can begin at the insertion site by contamination of the catheter from the patient's skin flora²⁵⁰ or during subsequent revisions. Short-term infection rates are reported to be 13%, and 10-year infection rates are 27%.²²³ Seventy percent of ventriculoperitoneal shunt infections occur within the first 2 months after placement.¹⁸³

CSF examination can be helpful in patients with signs and symptoms consistent with a shunt infection. Gram stain of ventricular fluid is often negative, but culture is sensitive. Subtle changes are noted in CSF and ventricular fluid cell counts or cytochemical findings.²⁸⁹ Patients with ventriculoatrial shunts often have signs and symptoms compatible with septicemia. In patients with ventriculoperitoneal shunts, an intraabdominal cyst may develop at the distal end of the catheter. Dysfunctions of the shunt secondary to development of infections often lead to signs and symptoms consistent with increased intracranial pressure. Standard therapy for ventriculoperitoneal shunt infections has been removal of the shunt system and administration of systemic antibiotics.^{250,289,291}

Peritoneal Dialysis Catheters

S. epidermidis is the bacterial pathogen most commonly isolated in peritoneal dialysis catheter infections,^{93,209} accounting for up to 50% of infections.²⁰⁹ These include catheter exit site infections as well as peritonitis.²⁰⁹ The prevalence of peritonitis in patients undergoing continuous ambulatory peritoneal dialysis is approximately 60%. Signs of peritonitis include fever, abdominal pain, and cloudy peritoneal dialysis fluid. Removal of the catheter usually is not necessary for successful therapy but may be required in refractory cases or when the catheter malfunctions. Antibiotics can be administered systemically as well as intraperitoneally through the dialysis fluid.⁷⁰

Prosthetic Valves

Coagulase-negative staphylococci are frequent pathogens causing prosthetic valve endocarditis, accounting for approximately 17% of cases.^{32,283} This is in contrast to native valve endocarditis for which coagulase-negative staphylococci are rarely isolated. Although many cases of coagulase-negative staphylococcal prosthetic valve endocarditis occur within 60 days of device implantation,¹⁵⁰ they can also occur as

late as 1 year after surgery, with inoculation of the organism at the time of surgery followed by abscess formation of the valvular ring being the likely mechanism.²⁹ Signs and symptoms can vary, but fever is the most common finding. Typical findings of endocarditis caused by other pathogens such as peripheral emboli can be mostly absent in coagulase-negative staphylococcal endocarditis, owing to the organism's indolent nature. Anemia is the abnormality identified most often by laboratory testing. Evaluation should include multiple blood cultures and echocardiography. The antimicrobial regimen for prosthetic valve endocarditis caused by coagulase-negative staphylococci usually involves vancomycin and rifampin for a minimum of 6 weeks along with gentamicin for the first 2 weeks because the majority of organisms are methicillin resistant.¹⁵ Surgery may be indicated when infection is complicated by perivalvular or myocardial abscesses.

Other Indwelling Medical Devices

Coagulase-negative staphylococci are involved in an expanded spectrum of infections involving indwelling medical devices.^{57,91} They include infections of prosthetic joints,^{71,125} vascular grafts,^{16,62} hemodialysis shunts,^{197,242,243} and pacemaker pockets.^{42,117,163,207} Additionally osteomyelitis secondary to *S. epidermidis* has been reported to occur after hemodialysis and in neonates after the use of a monitoring scalp electrode.¹⁹⁰

Native Valve Endocarditis

Approximately 7% of cases of native valve endocarditis are caused by coagulase-negative staphylococci, and *S. epidermidis* is the most frequently isolated species.⁴⁶ These infections usually are subacute and arise from transient bacteremia. Pathogenesis is thought to involve seeding of a previously damaged valve or endocarditis that had not been previously identified.^{6,19}

S. lugdunensis can cause acute, severe, and destructive endocarditis similar to *S. aureus* endocarditis,²⁷⁰ with most favorable outcomes occurring in patients who undergo valve replacement.⁵³ Most patients with *S. lugdunensis* endocarditis have been older than 50 years. Mortality rates are higher compared with infections by other species.¹³ Native aortic or mitral valves are involved most frequently.²⁶⁹ The perineum appears to have a high colonization rate of *S. lugdunensis*.¹²¹

Surgical Site Infections

Coagulase-negative staphylococci are the second most common cause of postoperative surgical site infections after *S. aureus*, according to National Nosocomial Infections Surveillance Report survey data.³⁸ Most infections are likely caused by the patient's own endogenous skin flora, but outbreaks originating from operating room personnel have been reported.²⁹ Outbreaks of *S. epidermidis* surgical site infections, such as mediastinitis and endocarditis, among patients who have undergone cardiac valve replacements also have been reported.^{28,218}

Urinary Tract Infections

S. saprophyticus is the most common coagulase-negative staphylococcal species that causes infections in both the upper and the lower urinary tracts.¹⁴⁷ These infections occur predominantly in young, healthy, sexually active women,^{122,147,166} during late summer and fall, with a pattern similar to that of sexually transmitted diseases.⁸¹ Recent sexual intercourse, outdoor swimming, and occupational meat processing have been identified as risk factors.⁸¹ *S. epidermidis* and other coagulase-negative staphylococci rarely cause urinary tract infections, but they have been noted to produce disease in older adults with urinary tract complications.^{96,153,184} Pyelonephritis caused by *S. epidermidis* have been described in healthy children.^{100,168}

Miscellaneous Infections

Endophthalmitis secondary to *S. epidermidis* has been reported in patients undergoing ocular surgery or trauma.^{17,31,210} One center reported coagulase-negative staphylococci as being the most common organisms isolated from patients with culture-positive endophthalmitis over a 20-year period, accounting for 38% of the cases.⁴⁰ Postoperative mediastinitis that develops after median sternotomy for open heart surgery can be caused by *S. epidermidis*.^{27,66,92} Primary osteomyelitis secondary to coagulase-negative staphylococci is a rare occurrence in

healthy children.¹⁹¹ *S. caprae*²⁵¹ and *S. lugdunensis*²³⁶ have been linked to bone and joint infections. Coagulase-negative staphylococci also have been implicated as a possible cause of toxic shock syndrome.⁴⁹ Rare cases of skin and soft tissue infections caused by *S. lugdunensis* have also been reported.^{143,171}

TREATMENT

Vancomycin is the drug of choice for most coagulase-negative staphylococcal infections, owing to the high prevalence of methicillin resistance especially among nosocomial strains.^{3,232,252} When susceptibility data are not available, vancomycin should be used for empirical therapy. If the coagulase-negative *Staphylococcus* is known to be susceptible to methicillin, oxacillin or nafcillin is the preferred therapeutic agent.^{211,233}

Most coagulase-negative staphylococci, particularly *S. epidermidis* and *S. haemolyticus*, are resistant to multiple antibiotics, including methicillin.^{7,9,43,56,69,88,101,245,256,275} Cross-resistance exists between penicillinase-resistant penicillins and cephalosporins. Therefore methicillin-resistant coagulase-negative staphylococci should be considered as cephalosporin resistant even if routine susceptibility testing indicates susceptibility to cephalosporins.^{93,119,148,232} Methicillin-resistant coagulase-negative staphylococci are often resistant to other antibiotics, such as clindamycin, erythromycin, and gentamicin.⁷ The *mecA* gene is responsible for methicillin resistance because it encodes a penicillin-binding protein (PBP2a) that interferes with the binding of β -lactams to the bacterial cell wall.^{107,115} The same mechanism accounts for methicillin resistance in *S. aureus*. Consistent detection of methicillin resistance for coagulase-negative staphylococci can be a challenging process in the clinical laboratory owing to heterogeneous expression of the *mecA* phenotype in minimal inhibitory concentration or disk diffusion testing with only a minority of the bacterial population expressing the resistant phenotype.^{7,115,232,288} To facilitate more reliable detection, the Clinical and Laboratory Standards Institute revised specific breakpoints for coagulase-negative staphylococci in 2007 (Table 81.5).⁴⁷ In addition, to enhance phenotypic expression of methicillin resistance, the use of lower incubation temperatures of 30°C to 35°C for prolonged periods and of increased sodium chloride content in culture medium is recommended.^{164,169,231} Molecular detection of the *mecA* gene is an accurate method to predict methicillin resistance.¹¹⁵

Coagulase-negative staphylococci were the first organisms in which glycopeptide resistance was recognized.²⁴⁵ A prolonged course of vancomycin is a well-recognized risk factor for the emergence of strains with decreased susceptibility to glycopeptides.^{24,288} Although they are uncommon occurrences, infections caused by these strains have been described and may become more common. Decreased susceptibility occurs more frequently to teicoplanin than to vancomycin.^{10,141,286} The minimal inhibitory concentrations of teicoplanin usually fall over a wide range, whereas vancomycin minimal inhibitory concentrations tend to remain more stable over a narrower range within the limits of susceptibility.²⁴ Intermediate resistance to vancomycin in coagulase-negative staphylococci has been rarely described.^{237,245,273} Thickened cell walls, as seen by electron microscopy and altered cell metabolism that affects vancomycin binding, may be associated with glycopeptide resistance mechanisms.¹⁰⁷

TABLE 81.5 Breakpoints for Antibiotic Susceptibility for Coagulase-Negative Staphylococci

	Oxacillin Susceptible	Oxacillin Intermediate	Oxacillin Resistant

<i>S. aureus</i>	≥13 mm	11–12 mm	≤10 mm

CoNS, Coagulase-negative staphylococci; MIC, minimal inhibitory concentration. Data from Clinical and Laboratory Standards Institute. *Performance testing for antimicrobial susceptibility testing*, 17th informational supplement M100-S17. Wayne, PA: 2007.

Gentamicin and rifampin are active against coagulase-negative staphylococci, but rapid emergence of resistance has limited their use as single-drug regimens.^{43,167,233} These two antibiotics have been shown to be synergistic with vancomycin against methicillin-resistant, coagulase-negative staphylococci.¹⁵⁷ Additionally rifampin has been used in neonates with persistent bacteremia to eradicate the organisms.^{260,271} Combination therapies utilizing gentamicin or rifampin are frequently used for prosthetic device infections including endocarditis and CSF shunt infections.

Quinupristin-dalfopristin,¹¹ linezolid,²³⁰ daptomycin,^{87,139,235} ceftaroline,²³⁴ and tigecycline^{80,139} have all demonstrated significant in vitro activities against coagulase-negative staphylococci and may have a role in the treatment of multidrug-resistant strains. However, there is a paucity of clinical efficacy data for these therapies, and many lack pediatric pharmacokinetic data to guide appropriate dosing. Linezolid resistance in coagulase-negative staphylococci has been described and linked to increased utilization.^{129,177}

PREVENTION

Preventing the development of coagulase-negative staphylococcal infection is difficult because of the ubiquitous and commensal nature of these organisms. A 3-year molecular analysis of coagulase-negative staphylococcal nosocomial infections in a neonatal intensive care unit showed that many of the infections were caused by clonal dissemination and potentially were preventable by hand washing, thus reducing the transmission rate from staff to patient or from patient to patient.²⁷⁶

Developing catheters that are both inert and resistant to bacterial colonization adherence has been only marginally successful.^{132,198,206} The technique of impregnating the surface of catheters with antibiotics or disinfectants appears promising.²⁶² Prophylactic antibiotics are administered routinely for surgical procedures involving placement of a prosthetic device or material. However, the antimicrobial of choice to prevent infections caused by coagulase-negative staphylococci varies among institutions.³ Vancomycin often is recommended for placement of a CSF shunt or prosthetic valve.

Infection control policies such as standardizing or “bundling” procedures for aseptic intravascular catheter placement and care is the single most important factor in preventing catheter-associated infections. Standard precautions should be used for methicillin-resistant, coagulase-negative staphylococci. For vancomycin-intermediate, coagulase-negative staphylococci, contact transmission precautions for multidrug-resistant organisms should be used.⁴

CONCLUSION

Coagulase-negative staphylococci, particularly *S. epidermidis*, are a major source of nosocomial infection in a variety of clinical situations. Most

infections occur in patients who have indwelling medical devices. Epidemiologic studies have been limited by the commensal nature of the organisms, but newer molecular tools may help investigators to gain further insight and to differentiate true infections from contaminants. Therapy can be complex because of the usual presence of an indwelling medical device and the multiple antimicrobial resistances of the organisms.

Group A, Group C, and Group G β -Hemolytic Streptococcal Infections

82

Linette Sande • Anthony R. Flores

Streptococcus pyogenes is the only organism within the group A β -hemolytic streptococci (GAS). GAS are among the most common pathogens that infect children and adolescents and are capable of causing a wide range of infections, including relatively benign pharyngitis and life-threatening invasive infections. Despite their uniform susceptibility to penicillin, GAS remain significant clinical and public health problems in this age group. Worldwide it is estimated that GAS are responsible for more than 500,000 deaths, the majority of which occur in under-developed countries.²⁶ GAS is unique among pyogenic streptococci in its ability to produce postinfectious sequelae such as acute rheumatic

fever and acute poststreptococcal glomerular nephritis (APSGN). Infections caused by GAS were brought to the forefront in the United States in the late 1990s with a resurgence of acute rheumatic fever^{96,158} and the appearance of serotype M1 and M3 strains causing severe morbidity and mortality.^{10,151}

ORGANISM

GAS are gram-positive cocci, generally less than 2 μm , and tend to grow in chains in liquid media. GAS produce clear zones of hemolysis

(β) on blood agar, differentiating them from streptococci producing partial (α) and nonhemolytic (γ) streptococci. Hemolysis is best observed when GAS are grown on agar containing 5% sheep blood. Some strains of GAS may appear to produce only partial hemolysis on blood agar plates. However, clear hemolysis can more easily be observed when grown anaerobically or by making a short cut or stab into the agar at the time of inoculation.⁷⁶ GAS are rarely nonhemolytic.^{73,75} They can be differentiated from other β -hemolytic streptococci by their group-specific polysaccharide in the cell wall, the basis for latex agglutination and enzyme immunoassays, or by inhibition of growth by bacitracin.

GAS are frequently categorized or typed based on serologically distinct surface proteins, the M proteins, or by sequencing the gene encoding the M protein, *emm*.^{42,43,76,87} The M protein is a major virulence factor of GAS. Acquired immunity to GAS is based, at least in part, on specific opsonic antibodies targeted against the M protein.⁸⁶ N-terminal sequence variation in the gene encoding the M protein has led to the description of more than 200 different *emm*-types,¹⁴ and many more are being added to a curated database publicly available through the Centers for Disease Control and Prevention (CDC).³⁰ Certain GAS M serotypes have been associated with specific diseases and can be classified as skin or pharyngitis “specialists”; however, some M serotypes have the capacity to cause both types of infection.¹⁶

The GAS cell is complex and contains many antigenic substances. Freshly isolated clinical strains are typically covered with a hyaluronic acid capsule that is structurally similar to that found in mammals, including humans, and thus is nonimmunogenic.^{19,50,79} The GAS capsule gives colonies a mucoid appearance. Recently some GAS serotypes (e.g., M4 and M22) have been shown to lack the genes necessary for hyaluronic acid biosynthesis.⁴⁸ Additionally a rise in the frequency of serotype M89 GAS has been linked to the absence of hyaluronic acid biosynthesis genes.^{155,164} The M protein is a major constituent of the cell surface, and proteins similar to M protein have been identified. Genes encoding M and M-like proteins (e.g., *emm* and *mrp*) are part of an *emm* gene superfamily. Also found on the cell surface, protruding through the hyaluronic acid capsule, are fimbriae composed of lipoteichoic acid¹³ that are frequently associated with M protein.⁴⁶ The surface proteins T and R and serum opacity factor are proteins of interest in part because of classification schemes based on each. The T protein is part of the GAS pilus structure,⁹⁸ and T-agglutination patterns are generally associated with specific M serotypes.⁷⁴ In strains that produce serum opacity factor, the serologically specific serum opacity factor proteins are closely correlated with a particular M serotype.¹⁵

The GAS cell surface contains a polysaccharide polymer of rhamnose with side chains of N-acetyl-glucosamine. The carbohydrate is found in sufficient quantities for antibody detection and forms the basis for group specificity originally described by Lancefield.⁸⁶ It has recently been recognized that the side chains of N-acetyl-glucosamine play a functional role in GAS pathogenesis.¹⁵⁶ Rigidity of the cell is provided by peptidoglycan consisting of alternating residues of N-acetyl-muramic acid and N-acetyl-glucosamine linked by a peptide bond. Lysozyme produced on mucosal surfaces and by phagocytic cells hydrolyzes the carbohydrate backbone, leading to lysis of the cell and release of bacterial fragments. Detection of the bacterial fragments by host pattern recognition receptors leads to initiation of the host immune response to infection. Some streptococci are able to modify their peptidoglycan, leading to lysozyme resistance,³⁸ and alter the host immune response. Whether GAS has this capability is unknown.

The innermost layer of the cell wall consists of the cell membrane composed of lipoprotein or lipid-protein complexes. Wall-less forms of streptococci, termed *L forms*, are osmotically fragile and lack the outermost constituents of the GAS cell wall. GAS *L forms* are of interest because of their resistance to penicillin⁵⁴ and their potential role in persistence.⁹⁵

In addition to cell surface components, GAS produces many extracellular products. Among these are two distinct hemolysins: streptolysin O and streptolysin S. Streptolysin O, designated so because of its oxygen lability, is toxic to erythrocytes and many other cell types, including phagocytes. Streptolysin O is produced by almost all GAS strains, is antigenic, and measurement of anti-streptolysin O (ASO) antibodies is used as an indicator of GAS infection. Streptolysin S is stable in the

presence of oxygen, heat labile, and not antigenic. Hemolysis on the surface of blood agar is the result of streptolysin S; streptolysin O results in hemolysis in the subsurface or in anaerobic conditions.

Several extracellular proteins allow the spread of GAS through tissue. Deoxyribonucleases (DNases A, B, C, and D) break down extracellular DNA and are believed to facilitate escape from neutrophil extracellular traps consisting in large part of DNA.²³ Spread through connective tissue is achieved through the action of hyaluronidases that enzymatically degrade hyaluronic acid, a major component of connective tissue. GAS streptokinase dissolves clots through conversion of plasminogen to plasmin. GAS produces a C5a peptidase that specifically cleaves C5a, inhibiting phagocyte recruitment. Originally thought to be a GAS superantigen, streptococcal pyrogenic exotoxin B (SpeB) is a potent protease critical in the pathogenesis of severe invasive disease.²⁷

The streptococcal pyrogenic exotoxins (Spe) constitute a family of bacterial superantigens believed to be associated with streptococcal toxic shock syndrome (TSS) and the pathogenesis of severe infections. SpeA and SpeC are bacteriophage-encoded and are associated with scarlet fever (i.e., scarlatinal toxins). Outbreaks of streptococcal TSS in the United States have been associated with strains producing SpeA.³³ Development of streptococcal TSS is multifactorial, and susceptibility may be associated with specific human leukocyte antigen haplotypes.⁸¹

TRANSMISSION AND EPIDEMIOLOGY

GAS are found almost exclusively in humans and rarely occur in other species.⁸⁷ Distinct and significant differences exist in the epidemiology and transmission of GAS based on the site of infection.^{118,161}

Streptococcal pharyngitis is one of the most common infections of childhood. Whereas GAS cause the majority of infections, strains of other serogroups, including groups C and G, may instead be involved. GAS pharyngitis occurs primarily in children aged 5 to 15 years, with the peak incidence occurring during the first school years. Severe epidemics may occur in conditions of overcrowding, including daycare centers,¹ residential facilities,¹¹⁷ and military barracks.¹⁶² The effect of crowding may explain, at least in part, the seasonal occurrence in temperate and cold climates. Contaminated foods (e.g., milk and egg salad) may result in outbreaks of GAS pharyngitis.^{70,92} Fomite contamination and airborne routes are unlikely to play any role in the spread of GAS pharyngitis.²⁹

The mechanism of spread is facilitated by close personal contact. Early studies demonstrated that large droplets or direct transfer of respiratory secretions containing large amounts of infectious bacteria is required.^{66,67} Experimental nonhuman primate studies¹⁵⁹ have elucidated the mechanisms of interpersonal GAS spread. The infection cycle consists of colonization, acute infection, and asymptomatic carrier phases of infection. During acute infection, GAS are present in large amounts in both the anterior nares and throat.⁶⁷ Although the acute symptomatic phase lasts only a few days, left untreated, the organism can persist for weeks in the absence of symptoms. During the asymptomatic carrier phase, bacterial burden decreases in the anterior nares and persists at lower numbers in the throat. Early studies also demonstrated that GAS in the asymptomatic carrier phase possess less hyaluronic acid capsule¹²⁷ and M protein.¹²⁴ The end result is that asymptomatic carriers are less likely to transmit the organism to close contacts than are those acutely infected. Antibiotic therapy rapidly reduces the bacterial burden and in most cases eradicates GAS from the throat. Thus, most patients are considerably less contagious within 24 hours of initiation of antibiotic therapy, reducing the risk for spread to contacts.¹³⁹

The epidemiology and transmission of GAS skin infections is markedly different compared to throat infections. Prevalence of GAS skin infections appears to be influenced most by climate and level of hygiene. In contrast to throat infections, the peak age of incidence in impetigo and pyoderma is in children 2 to 5 years of age (i.e., preschool aged). GAS skin infections occur more frequently in hot or tropical climates²⁵ and, in temperate climates, infections are more common during the summer months.⁴⁵ Infection causing impetigo and pyoderma appears to be facilitated by disruption of the skin by trauma, insect bites, or preexisting skin disorders (e.g., eczema). The role of fomites and

environmental contamination in the spread of GAS skin infections remains undefined.

Prospective studies on the transmission of streptococcal impetigo demonstrated that GAS initially colonize unbroken skin.⁴⁵ GAS skin colonization preceded development of impetiginous lesions by an average of 10 days.

Measures to prevent spread of GAS infections vary in their effectiveness. Spread of throat or skin infection within a family often occurs before the index case is identified and isolated or treated. In epidemic situations, especially situations involving cases of rheumatic fever or acute nephritis, a culture survey with treatment of all individuals with positive cultures (mass prophylaxis) may be indicated.¹⁵² Reduction of crowding, especially in sleeping quarters, seems to be an effective long-term method of minimizing the incidence of transmission of streptococcal sore throat among some groups.

In families in which persistence or recurrence of streptococcal infection is a problem, simultaneous throat culture and culture of skin lesions of all members and treatment of all who have positive results have been successful in eradicating the organism. Control of environmental contamination would be expected to have little or no influence on the spread of GAS respiratory infections, although it possibly has an effect in controlling skin or wound infections. It also is suggested that family toothbrushes may have a role in the intrafamilial transmission of GAS. More recent guidelines have suggested, however, that performing cultures of all family members in instances in which invasive GAS infections occur is not always necessary. Because of reported instances in which secondary cases have occurred, this guideline remains controversial.^{29,121,152}

PATHOGENESIS

Despite the numerous studies focusing on the pathogenesis of GAS infections, we understand little of mechanisms that give GAS predilection for certain body sites or why certain M serotypes are more frequently found in pharyngitis and yet others in skin infections. Infection begins with successful colonization of skin or pharyngeal epithelial surfaces. Initial interaction of GAS with epithelial surfaces is mediated by fimbriae and pili, believed to overcome the negative electrostatic forces between bacterial and host cell surfaces. More specific binding occurs through pili, M protein, hyaluronic acid capsule, and numerous fibronectin binding proteins. The complement of fibronectin binding proteins identified in GAS include proteins F1 (Prtf1) and F2 (Prtf2), SfbI, SfbII, FBP54, and others.¹⁰⁷

Steps in initial colonization also require successful competition between resident flora on either the skin or pharyngeal epithelium. α -Hemolytic or viridans streptococci may interfere with throat colonization, and GAS elaborates bacteriocin-like substances that may facilitate competition.¹⁰⁷ Colonization of skin surfaces appears to be enhanced by physical removal of local bacterial flora.⁴

Several GAS virulence determinants participate in tissue invasion. Immune evasion is facilitated by expression of the antiphagocytic hyaluronic acid capsule, M protein, and IdeS (also known as Mac, which cleaves immunoglobulin [Ig]G bound to GAS); breakdown of neutrophil extracellular traps and host tissues by DNases, hyaluronidases, and the cysteine protease SpeB; breakdown of chemoattractants by *S. pyogenes* cell envelope protease (SpyCEP) (cleaves IL-8), C5a peptidase (cleaves C5a); and others, including streptococcal inhibitor of complement (SIC), streptolysin O, and streptokinase. Together these virulence factors subvert immune defenses and facilitate spread through tissues.

Recently researchers have shed light on the in vivo molecular events that lead to invasive GAS infections. Many of the GAS virulence factors required for invasive infection are normally repressed by the CovRS two-component regulatory system. During invasive infection of serotype M1, mutations in the genes encoding the CovRS proteins result in de-repression (i.e., increased expression) of virulence factors, leading to more severe disease.^{41,143} Extensive whole-genome sequencing studies of serotype M3¹³⁰ and M1¹⁰⁵ GAS isolates from human pharyngitis and invasive infections demonstrated that mutations in *covS* occur at a significantly higher frequency in isolates from invasive disease in contrast to pharyngitis. Moreover examination of paired superficial and invasive

isolates from the same patient suggest that *covRS* mutation may facilitate the breaching of epithelial barriers leading to dissemination and invasive disease.^{49,55}

We understand little of the mechanisms leading to early host defense against GAS infection. Although specific antibody targeted against the M protein promotes phagocytosis, it usually does not develop until 6 to 8 weeks after initial infection.⁴⁰ Rather than act during initial infection, type-specific antibody against the M protein more likely prevents reinfection by the same serologic type. Thus, in the early stages of infection, protection via phagocytosis by monocytes and polymorphonuclear leukocytes appears to be the primary mechanism of defense.

The rash and other toxic manifestations of scarlet fever have been attributed to the development of hypersensitivity to the pyrogenic toxins.¹⁸ Toxic manifestations that have been noted in GAS TSS also may result from a direct influence of the pyrogenic exotoxins on lymphokines, such as tumor necrosis factor.¹⁴² Hypersensitivity to other streptococcal products also may contribute to the manifestations of streptococcal disease.

Theories about the pathogenetic mechanism leading to the development of the nonsuppurative complications of streptococcal infections, acute rheumatic fever, and acute glomerulonephritis. Most of these hypotheses invoke immunologic processes in one way or another.^{71,157} A major impediment toward clarifying the pathogenetic mechanism responsible for the development of nonsuppurative sequelae has been the lack of an appropriate animal model for study.

CLINICAL MANIFESTATIONS

Pharyngitis or tonsillitis caused by GAS has a brief incubation period of 12 hours to 4 days. Acute illness is characterized by abrupt onset of sore throat, malaise, fever, and headache. Children may present with nausea, vomiting, and abdominal pain. Severity can vary greatly from subclinical to a toxic appearance. Common physical findings include fever, erythema, edema, and lymphoid hyperplasia of the posterior pharynx, enlarged, hyperemic tonsils, exudate on the pharyngeal and tonsillar surfaces, and enlarged, tender lymph nodes at the mandibular angle.

Clinical manifestations generally subside spontaneously in 3 to 5 days in the absence of suppurative complications (e.g., otitis media, sinusitis, and peritonsillar abscess). Prompt antibiotic therapy (e.g., penicillin) shortens the period of fever, toxicity, and infectivity.^{84,106,119} After acute streptococcal infection of the upper respiratory tract, the average latent period for glomerulonephritis is 10 days and the latent period for acute rheumatic fever is 18 days.¹⁶¹

Localized pharyngeal infection is less common in younger children, especially infants. An infantile form of streptococcal infection, streptococcal childhood fever, may be more prolonged, with persistent low-grade fever, generalized lymphadenopathy, and persistent serous nasal discharge. The term *streptococcosis* more correctly indicates the changing clinical picture with age analogous to that of tuberculosis.¹¹⁶

Infection with strains that elaborate streptococcal pyrogenic exotoxins may manifest as scarlet fever. Most commonly scarlet fever is associated with pharyngeal infection; however, it may also follow infection of wounds or puerperal sepsis. The characteristic rash is erythematous and finely punctate, with centrifugal spread beginning on the upper chest or trunk. The rash usually appears on the second day of illness, blanches with pressure, and spreads to cover the entire body within several hours to days. Lines of deeper red may be noted in the skinfolds of the neck, axillae, elbows, groin, and knees (Pastia's lines). The tongue may take on a strawberry appearance and become swollen and red. The skin may take on a sandpaper texture because of the occlusion of sweat glands, a particularly useful feature for diagnosis in dark-skinned people. Severe forms may be associated with local and hematogenous spread of the organism (i.e., septic scarlet fever) or toxemia (i.e., toxic scarlet fever). Rarely, scarlet fever may be complicated by arthritis, jaundice, and hydrops of the gallbladder. Severe manifestations are less frequent with the use of antibiotics.

Impetigo caused by GAS develops days or weeks after colonization on normal skin with an average latent period of 10 days.⁴⁵ The infection is usually painless in contrast to pharyngitis. Vesicles with minimal

surrounding erythema rapidly develop into pustules and then into a thick, honey-colored crust that may persist for days or weeks. GAS impetigo does not involve the dermis, and depigmentation may be seen on healing but does not scar.

Strains of GAS that cause skin infections differ from those associated with tonsillitis and pharyngitis. The serologic types associated with skin infection tend to be higher-numbered M-types because of their more recent discovery. A small number of serotypes are capable of causing both pharyngitis and skin infections.¹⁶

APSGN may develop after cutaneous infection by a nephritogenic strain. Whereas rheumatic fever has not been proved to develop after skin infections with GAS, a clear association exists between GAS skin infections and rheumatic heart disease especially in Pacific populations.¹⁰⁹ The latent period for APSGN after skin infection is longer, 3 weeks on average, than is seen after pharyngitis (10 days).⁷⁷

Erysipelas is a superficial streptococcal infection of the skin and sometimes adjacent mucous membranes. Three features distinguish erysipelas clinically from other forms of skin infection: (1) lesions are raised above the level of the surrounding skin, (2) a clear line of demarcation distinguishes infected from uninfected areas, and (3) lesions are a brilliant salmon-red color. Erysipelas is more common in infants and young children and most often involves the face. Lesions may be associated with wounds, an area of dermatosis (e.g., eczema), or the umbilical stump of a newborn. The cutaneous inflammation of erysipelas is often accompanied by systemic manifestations of toxicity observed in other forms of streptococcal infection.

If nothing else, GAS is notable for its ability to cause a wide range of infections. In addition to those already mentioned, suppurative complications of upper respiratory tract infection include otitis media, retropharyngeal or peritonsillar abscess, sinusitis, mastoiditis, pneumonia, and empyema. GAS are frequently isolated in cultures from peritonsillar abscesses¹⁴⁴ and likely act in concert with anaerobic bacteria to produce this entity.²¹ Classically acute puerperal sepsis has been associated with GAS. Infection of the skin and subcutaneous tissues (streptococcal cellulitis) may complicate burns, wounds, surgical incisions, or seemingly mild trauma. More severe infections of the deeper subcutaneous tissues and fascia with rapid spread and necrosis (necrotizing fasciitis or streptococcal gangrene) also are associated with GAS. These bacteria are a common cause of perianal cellulitis and vaginitis in children.^{7,80} Subpectoral abscesses and empyemas may develop as complications of streptococcal infections of the thumb and index finger as a result of the lymphatic drainage of that part of the hand.⁷ Septic complications of varicella, including varicella gangrenosa,^{24,138} osteomyelitis (especially in infants),⁶⁴ hand and foot syndrome,⁶⁵ blistering distal dactylitis,⁶⁹ necrotizing fasciitis, and TSS, are associated with β -hemolytic streptococci.

STREPTOCOCCAL UPPER RESPIRATORY TRACT CARRIER STATE

In addition to causing a wide range of diseases, asymptomatic carriage of GAS is a common occurrence among children and adolescents. Depending on the population studied, rates of GAS carriage range from 5% to 15% among children,¹²⁹ a rate greatly exceeding that of any disease caused by GAS. Very early studies demonstrated that pharyngeal carriers of GAS are less dangerous to others because they harbor fewer organisms and rarely spread the organism to close contacts.^{66,67} However, multiple epidemiologic studies have shown that close contacts may harbor virulent organisms in the absence of symptoms.^{34,99} Thus carriage represents a diagnostic and therapeutic dilemma for the clinician. The epidemiologic and immunologic reasons for the establishment and continuation of the carrier state are an active area of investigation.

A combination of host and bacterial factors are believed to contribute to the GAS carrier state. As opposed to true infection, in which an individual has the presence of the organism and evidence for an immunologic response, GAS carriers may harbor the organism for long periods in the absence of a host immune response.⁷⁶ Few studies have examined the bacterial or host factors that lead to persistent colonization by GAS. Bacterial studies suggest that GAS are able to internalize into epithelial cells and that internalization is associated with the presence

of certain fibronectin-binding proteins.^{12,104} Because penicillin does not effectively penetrate the epithelial cell, intriguingly, some have suggested that internalization of GAS into pharyngeal epithelial cells contributes to persistence despite antibiotic therapy.⁷⁸

TREATMENT

GAS remain universally susceptible to penicillin *in vitro*. Oral penicillin V and intramuscular benzathine penicillin are the drugs of choice for the treatment of GAS, except in patients with a penicillin allergy.⁵⁸ The advantages of penicillin include a narrow spectrum of activity, proven efficacy, and low cost.⁵⁸

Initial studies on the efficacy of penicillin for the primary prevention of acute rheumatic fever were conducted with military recruits in the 1950s.^{39,161,162} Initial studies involved the use of injectable penicillin suspended in either sesame oil or peanut oil, and they showed therapeutic penicillin concentrations in serum for 9 to 10 days.¹⁶¹ Later studies found an equal bacterial eradication rate of 10 days with either oral penicillin G or injectable benzathine penicillin.¹⁶² Oral penicillin remains the first-line therapy because benzathine penicillin G is associated with pain and increased risk of allergic reactions.¹¹² However, in certain situations in which adherence to regimen or follow-up is not possible, intramuscular benzathine penicillin is preferred.

The regimen that has been established is 10 days of penicillin V treatment or a single dose of benzathine penicillin to prevent acute rheumatic fever.^{17,58} The most recent guidelines by the Infectious Diseases Society of America (IDSA) for the prevention of rheumatic fever and treatment of acute streptococcal pharyngitis¹³³ recommend a dose of penicillin V for most children of 250 mg twice a day, and the dose usually recommended for adolescents and adults is 500 mg two or three times per day (see Table 82.1).¹³³ Penicillin V is preferred to penicillin G because it is more resistant to gastric acid. Although penicillin V is the recommended drug, many physicians prescribe amoxicillin because of its improved taste. An oral time-released formulation of amoxicillin was approved by the US Food and Drug Administration (FDA) for once daily therapy for patients 12 years of age and older.¹³³

For patients with a penicillin allergy, a 10-day oral course of a narrow spectrum cephalosporin (e.g., cefadroxil or cephalexin) is recommended. Some studies have shown that 10 days of an oral cephalosporin is superior to a 10 day-course of oral penicillin.^{63,115} Other studies suggest that treatment with 5 days of an oral broad-spectrum cephalosporin is comparable to treatment with 10 days of oral penicillin in the eradication of GAS tonsillopharyngitis.^{58,114} However, at present, these shorter regimens have not been approved by the FDA. In the past, erythromycin was the drug of choice for penicillin-allergic patients, but it has been replaced by newer medications since they have lower rates of gastrointestinal side effects and easier administration regimens.^{31,53,133} In patients with an immediate hypersensitivity (anaphylactic type) to penicillin, cephalosporins should be avoided, and macrolides (erythromycin or clarithromycin), azithromycin (an azalide), or clindamycin (a lincosamide) should be used. Recommended doses are shown in Table 82.1.

Macrolide resistance has been documented in many countries and remains an ongoing concern for the treatment of GAS infections.^{53,90} Although erythromycin-resistant organisms were found in the 1950s, it was not until the 1970s that clinically significant macrolide resistance was noted.⁵³ Resistance to macrolides occurs by one of two mechanisms: an active efflux pump (M phenotype) related to enzymes encoded for by *mef* genes or ribosomal target site modification by methylation (*erm* genes), which causes coresistance to macrolide, lincosamide, and streptogramin (MLS) antibiotics (MLS phenotype).⁹⁰ Countries such as Japan, Finland, Italy, and the United States have reported treatment failures due to macrolide resistance.⁵³ A study in Finland¹²⁸ reported a decrease in the use of macrolide antibiotics from 2.40 defined daily doses per 1000 inhabitants per day in 1991 to 1.38 in 1992, after national recommendations were made to reduce the number of macrolides prescribed for respiratory and skin infections. This resulted in a decrease in macrolide resistance from 16.5% in 1992 to 8.6% in 1996.¹²⁸ Although the rate of resistance in the United States is relatively low compared with much of the rest of the world, a recent U.S. multicenter surveillance study⁶⁴ found an overall adjusted rate of macrolide resistance in GAS

TABLE 82.1 Antibiotic Regimens Recommended for Group A Streptococcal Pharyngitis

Drug, Route	Dose or Dosage	Duration or Quantity	Recommendation Strength, Quality ^a
Individuals Without Penicillin Allergy			
Penicillin V, oral	Children: 250 mg twice daily or 3 times daily; adolescents and adults: 250 mg 4 times daily or 500 mg twice daily	10 days	Strong, high
Amoxicillin, oral	50 mg/kg once daily (max = 1 g); alternate: 25 mg/kg (max = 500 mg) twice daily	10 days	Strong, high
Benzathine penicillin G, intramuscular	<27 kg: 600,000 U ≥27 kg: 1,200,000 U	1 dose	Strong, high
Individuals With Penicillin Allergy			
Cephalexin, ^b oral	20 mg/kg/dose twice daily (max = 500 mg/dose)	10 days	Strong, high
Cefadroxil, ^b oral	30 mg/kg once daily (max = 1 g)	10 days	Strong, high
Clindamycin, oral	7 mg/kg/dose 3 times daily (max = 300 mg/dose)	10 days	Strong, moderate
Azithromycin, ^c oral	12 mg/kg once daily (max = 500 mg)	5 days	Strong, moderate
Clarithromycin, ^c oral	7.5 mg/kg/dose twice daily (max = 250 mg/dose)	10 days	Strong, moderate

^aInformation is based on Grading of Recommendations Assessment, Development, and Evaluation criteria.

^bAvoid in individuals with immediate-type hypersensitivity to penicillin.

^cResistance of group A *Streptococcus* to these agents is well known and varies geographically and temporally.

For other acceptable alternatives, see text. The following are not acceptable: sulfonamides, trimethoprim, tetracyclines, and fluoroquinolones.

From Shulman ST, Bisno AL, Clegg HW, et al. Clinical practice guideline for the diagnosis and management of group A streptococcal pharyngitis: 2012 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2012;55(10):e86–102.

of 5.2%. This represents a near twofold increase from rates reported in the United States in the 1990s. In recent years, macrolide resistance rates in the U.S. have ranged between 5% and 8%.⁵ To avoid further increases in macrolide resistance that may result in treatment failures and acute rheumatic fever, some experts recommend that macrolide antibiotics be reserved for the treatment of GAS infections in patients with anaphylactic-type penicillin allergy.⁹⁰

Certain broad-spectrum antibiotics should not be used against GAS. There is high prevalence of resistance to tetracycline and therefore it should not be used. Sulfonamides and trimethoprim-sulfamethoxazole should be avoided because they do not eradicate GAS from the pharynx. Ciprofloxacin has limited activity against GAS and therefore should not be used. Newer fluoroquinolones such as levofloxacin and moxifloxacin have shown in vitro activity against GAS, but should not be used because they are expensive and provide an excessive broad-spectrum activity.^{36,57,58,133}

Even though penicillin remains the drug of choice in the treatment of GAS, penicillin treatment failures of 20% to 40% or higher have been reported.¹¹³ It has been documented more often after oral penicillin than after benzathine penicillin.⁴⁴ Possible explanations for penicillin treatment failures include lack of compliance, penicillin tolerance, and carrier state.^{58,113} Other considerations that have been proposed include copathogens in the pharynx^{62,113,115,137} and antibiotic suppression of immunity.^{20,58,163} Some authors have suggested that certain β -lactamase-producing organisms such as *Staphylococcus aureus*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and anaerobes may be present in the pharynx during a GAS infection and inactivate penicillin. They argue that this may be one of the reasons for the superiority of β -lactamase stable antibiotics in cases of penicillin failures.¹¹⁴ Studies from the 1940s and 1950s documented that antibiotics given shortly after onset of symptoms (within 24 to 48 hours) could suppress the immune response to the infection.^{20,163} Other studies did not show a difference whether treatment was started early or delayed for 48 hours.⁵⁹ Penicillin therapy is effective in preventing rheumatic fever when started within 9 days after the onset of illness.^{28,58,133} Delaying therapy for 24 to 48 hours until culture results are known does not increase the risk of rheumatic fever.^{58,133} However, therapy should not be delayed in patients who appear toxic or are severely ill.

At present, recommendations in the management of GAS pharyngitis in children include obtaining a streptococcal rapid antigen detection test, with initiation of treatment when positive. Negative rapid antigen detection tests should be backed by a throat culture. Follow-up cultures in patients treated for GAS are no longer routinely recommended and

should only be performed in those who remain symptomatic, have recurrence of symptoms, or have a history of rheumatic fever.^{17,58,133} Children with recurrence of GAS pharyngitis symptoms after completing a 10-day course of a recommended oral antimicrobial agent can be retreated with the same antimicrobial agent, given an alternative oral drug, or given an intramuscular dose of penicillin G benzathine, especially if noncompliance is suspected. Alternative drugs include a narrow-spectrum cephalosporin, amoxicillin-clavulanate, clindamycin, a macrolide, azalide, or penicillin plus rifampin.^{5,58,133}

Individuals found to have a positive rapid antigen detection test or throat culture without clinical evidence of infection or rise in antistreptococcal titers are considered chronic streptococcal carriers and do not need to be treated with antibiotics. However, because it may be difficult to distinguish a carrier state from true GAS infection when a viral upper respiratory infection develops in a carrier, appropriate antibiotics should be prescribed to any patient with acute pharyngitis and evidence of GAS from a positive rapid antigen detection test or throat culture.^{5,58,133}

Although guidelines from the American Heart Association and from the IDSA exist for the treatment of GAS tonsillopharyngitis, no official guidelines exist for the treatment of streptococcal impetigo. For patients with a few lesions, topical therapy with mupirocin or retapamulin ointment may be useful for limiting person-to-person spread and for eradicating localized disease.² In more severe cases with multiple lesions or with nonbullous impetigo in multiple family members, child care groups, or athletic teams, impetigo should be treated with systemic antimicrobials.⁵ Oral or parenteral penicillin may be used in the same doses as those for streptococcal infections. Regimens with first-generation cephalosporins or macrolides should be used for penicillin-allergic patients. With the increase in skin and soft tissue infections due to methicillin-resistant *Staphylococcus aureus* (MRSA), obtaining appropriate cultures and treating with antibiotics to cover this possible pathogen must also be considered.

Although treatment with penicillin has been shown to prevent the development of rheumatic fever, no definitive evidence exists that antimicrobial therapy after treatment of streptococcal skin infections prevents acute poststreptococcal glomerulonephritis.²

Otitis media and cervical adenitis due to GAS can be treated with the same regimens used for the treatment of streptococcal pharyngitis. Systemic parenteral antimicrobial therapy is indicated for severe infections, such as septicemia, pneumonia, endocarditis, meningitis, arthritis, osteomyelitis, erysipelas, necrotizing fasciitis, neonatal omphalitis, and streptococcal TSS. Treatment often is prolonged (2 to 6 weeks).⁵ In the case of TSS and necrotizing fasciitis, clindamycin is also recommended

because it is a protein-synthesis inhibitor and can neutralize bacterial toxins. Drainage of any lesions is warranted. Intravenous immunoglobulin (IVIG) can be considered as adjunctive therapy for GAS-related TSS or necrotizing fasciitis if the patient is severely ill.⁵

PREVENTION

Treatment of GAS pharyngitis with antimicrobials aims to prevent rheumatic fever through primary prevention. Prevention of recurrence of rheumatic fever (secondary prevention) requires continuous antimicrobial prophylaxis (see Chapter 29). A meta-analysis of 10 trials on primary prevention of rheumatic fever, which were carried out in the United States during 1950 to 1961, revealed that, although the methodology of the studies was poor, administration of antibiotics in patients with GAS infection reduced the risk of acute rheumatic fever by nearly 70%.¹²² A subgroup analysis showed that the risk reduction was 80% when treated with intramuscular penicillin.¹²²

Although the incidence of acute rheumatic fever has decreased in the developing world for the past 50 years, outbreaks in the community and the military continue to occur, and acute rheumatic fever remains a major cause of morbidity and mortality in the developing world.³⁵ Current strategies for disease prevention include infection-control measures such as isolation, appropriate hygiene measures for postpartum and postsurgical patients, and establishing nationwide surveillance systems.³⁵ During episodes of epidemic GAS infections, mass prophylaxis with penicillin, particularly intramuscular benzathine penicillin G, has been shown to be effective.

Children in the outpatient setting being treated for a GAS infection may return to daycare or school after 24 hours of treatment. For hospitalized children, droplet precautions are recommended for GAS pharyngitis or pneumonia until 24 hours after initiation of appropriate antimicrobial therapy. In the case of burns with secondary GAS infection and extensive or draining cutaneous infections that cannot be covered by dressings, patients should remain in contact precautions for at least 24 hours after the start of appropriate therapy.² Asymptomatic household contacts do not require diagnostic evaluation or chemoprophylaxis, unless exposure occurs during outbreaks or the contacts are at higher risk for developing sequelae of infection.⁶

In certain cases of GAS pharyngitis refractory to treatment, tonsillectomy has been performed, but at present, there are insufficient data to recommend routine tonsillectomy as part of the management of GAS pharyngeal infections.

Despite the use of antimicrobials, the persistence of acute rheumatic fever and its associated morbidity and mortality, especially in the developing world, has led to intensive research in vaccine development against GAS. However, despite more than 70 years of research, a commercial vaccine is still not available.³⁵ One of the main concerns for development of vaccines based on the M protein was the possibility of causing autoantibodies that could cross-react with heart, skeletal muscle, brain, and glomerular basement membrane tissues.^{31,35} However, multivalent M protein-based strategies are at the forefront of GAS vaccine development. A 26-valent vaccine has been developed and shown to be both safe and immunogenic in healthy adults.^{82,94} Such a vaccine would include 86% of the serotypes causing GAS pharyngitis, which could prevent 49% to 63% of invasive GAS infections among children and 43% to 50% among elderly individuals, with similar decreases in the number of deaths.¹⁰⁸ However, because of the geographic and temporal differences in M-types between countries, this vaccine may not be as effective in other countries, such as Japan, Ethiopia, or New Zealand.^{35,125} More recently, a 30-valent vaccine has been developed, and early studies suggest that the vaccine may have broader coverage than originally anticipated.³⁷ Other components of GAS have been under investigation as potential candidates in the development of a vaccine. These include carbohydrate antigens, adhesins, C5a peptidase, and the GAS pilus.³¹ Mucosal vaccines to GAS are also under investigation because mouse studies have found induction of specific IgA production during intranasal administration of vaccine, along with IgG production in serum.³¹ Further research is needed in GAS vaccine development, with a goal of vaccines that may be useful globally.

PEDIATRIC AUTOIMMUNE NEUROPSYCHIATRIC DISORDERS ASSOCIATED WITH STREPTOCOCCAL INFECTIONS

Pediatric autoimmune neuropsychiatric disorders associated with streptococcal (PANDAS) infection is an autoimmune condition with obsessive-compulsive disorder (OCD) or tic disorder manifestations associated with GAS. Initially it was described as pediatric infection-triggered autoimmune neuropsychiatric disorders (PITANDS) by Allen, Leonard, and Swedo³ in a four-patient case series and later coined as PANDAS by Swedo and associates¹⁴⁸ in a larger study involving 50 patients that established the diagnostic criteria, which include the following:

1. Presence of OCD and/or a tic disorder meeting lifetime *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) diagnostic criteria
2. Age at onset between 3 years of age and the beginning of puberty
3. Clinical course characterized by the abrupt onset of symptoms or by dramatic symptom exacerbations
4. Temporal association with GAS infection, diagnosed by positive throat culture and/or elevated anti-GAS antibody titers
5. Association with neurologic abnormalities such as choreiform movements or tics

This proposed disorder is currently a hypothesis, and it remains a controversial topic. Several authors believe this disorder is a separate entity and recommend treatment and prophylaxis. Others argue that it is only a hypothesis and that further evidence with double-blinded studies is needed before recommending treatment and prevention for children given a diagnosis of PANDAS.

Proposed Pathogenesis

The hypothesis for PANDAS involves several factors, including pathologic strains of group A streptococcal bacteria, host susceptibility (e.g., genetics, development, or other), and abnormal immune response.¹⁵⁰ A pathogenesis model has been proposed to describe the disorder (Fig. 82.1).¹⁴⁵ Ongoing research is being conducted to understand the pathologic mechanisms involved in the PANDAS subgroup.

As part of the diagnostic criteria, temporal association with GAS infection and neuropsychiatric exacerbation is very important. It is essential to distinguish exacerbations of PANDAS due to GAS infection from the waxing and waning course seen in Tourette disorder and some cases of childhood-onset OCD.¹⁴⁵

According to Swedo,¹⁴⁵ host susceptibility is thought to result from genetic, developmental, and immunologic factors. Children in the PANDAS subgroup may have similar genetic susceptibility for post-streptococcal sequelae as children with Sydenham chorea. Development also seems to play a role in the pathogenesis of PANDAS because the peak age of onset of symptoms is 6 to 7 years and prepubertal onset is characteristic. PANDAS is described as an autoimmune process, and many think that there are antineuronal cross-reactive antibodies similar to the autoantibodies found in Sydenham chorea.¹⁴⁵ These antibodies

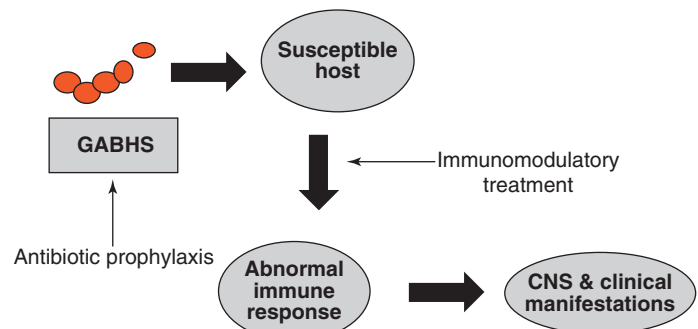

FIG. 82.1 Model of pathogenesis for pediatric autoimmune neuropsychiatric disorder associated with streptococcal infections. CNS, Central nervous system; GABHS, group A β -hemolytic *Streptococcus*. (From Swedo SE: Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections [PANDAS]. *Mol Psychiatry*. 2002;7:S24.)

are meant to react against group A *Streptococcus* epitopes, but, in the case of PANDAS, they cross-react with cells in the basal ganglia.⁶¹ Studies using magnetic resonance imaging volumetric scans have shown bilateral enlargements of the caudate, putamen, and globus pallidus among patients in the PANDAS subgroup.^{60,61}

Diagnosis

The diagnostic criteria defined by Swedo and colleagues during the description of the first 50 cases of PANDAS aimed to define a homogeneous subgroup of patients with OCD and tic disorders who had dramatic acute exacerbations usually following a GAS infection.^{148,150} However, in the initial cohort, other psychiatric comorbidities were also found frequently, particularly attention-deficit/hyperactivity disorder (ADHD), affective disorders, and anxiety disorders. More recently other authors proposed the criteria be expanded to include related disorders such as ADHD¹¹¹ and anorexia.¹⁴¹ In terms of the age at onset criterion, the authors based this on historical data showing that rheumatic fever and other poststreptococcal sequelae are rare before the age of 3 years and after the age of 12 years. Protective serum antibodies against streptococcal infections were found in 98% of healthy 12-year-old controls in a study by Fischetti.⁴⁷ OCD related to PANDAS usually can be distinguished from other forms of OCD because children in the PANDAS subgroup typically have a sudden onset of symptoms, reaching a peak in 24 to 48 hours, whereas in non-PANDAS OCD there is a more gradual onset of obsessions and compulsions. The authors also proposed that exacerbations of neuropsychiatric symptoms begin within 7 to 14 days after an infection with GAS and usually occur simultaneously.¹⁵⁰ However, since streptococcal infections are so common during childhood, for a child to fit this diagnostic criterion there should be prospective evaluation and documentation of at least two episodes of neuropsychiatric symptoms that correlate with streptococcal infections, as well as documentation of evidence of negative throat cultures or antibody titers when the patient goes into remission of neuropsychiatric symptoms. The last diagnostic criterion involves the presence of neurologic abnormalities during periods of symptom exacerbation. Choreiform movements seen in PANDAS patients are small, jerky movements that occur in an irregular and arrhythmic pattern in different muscles,¹⁴⁸ described as fine piano-playing movements of the fingers. Patients with a diagnosis of rheumatic fever, including chorea, should be excluded from the PANDAS subgroup.¹⁴⁸

Children considered to have possible PANDAS syndrome who have symptoms suggestive of streptococcal infection should undergo evaluation for GAS infection. Rapid streptococcal antigen tests should be obtained, as well as a throat culture if the antigen test was negative. In patients with a negative throat culture, ASO and anti-DNase B titers could be obtained if the onset of PANDAS was at least 4 to 6 weeks prior. With acute exacerbations of tics or OCD symptoms, patients should be reevaluated for an acute infection due to GAS.¹⁴⁶

A diagnostic marker present in children with rheumatic fever, D8/17, has been postulated to also identify children with PANDAS,¹⁴⁹ but its use in diagnosis of PANDAS remains controversial.¹³¹

Treatment

All patients who have an acute GAS infection should receive appropriate antibiotic therapy, usually with penicillin, because it remains the drug of choice. Treatment of the streptococcal infection has been noted by some authors to improve or cure the neuropsychiatric symptoms of PANDAS. A small prospective study of 12 patients showed resolution of symptoms of new-onset OCD, anxiety, and tics within an average of 14 days after starting treatment with an antibiotic (either penicillin, amoxicillin, amoxicillin/clavulanate, or a cephalosporin).¹⁰³ Every recurrent episode of PANDAS was associated with a GAS infection, and all patients with recurrences showed improvement after treatment with antibiotics.¹⁰³ However, this was a small study and not a double-blinded, randomized controlled trial.

Children with a significant tic disorder or OCD should receive appropriate psychiatric medications as necessary. Cognitive behavioral therapy also may be beneficial in the treatment of OCD. These treatments are commonly used in tics and OCD not related to PANDAS and have also been used for treatment of neuropsychiatric symptoms in patients given a diagnosis of PANDAS.⁸⁵

Immunomodulators have been used in therapeutic trials based on the proposed model of immunologic dysfunction. One study reported benefits in patients fulfilling criteria for PANDAS in the group treated with plasma exchange as well as in the group treated with IVIG.¹¹⁰ This study, however, was limited by small sample size, highly selective recruitment, and limited comparisons with controls. In addition, nearly two-thirds of patients receiving active treatment experienced adverse effects.¹¹⁰ A small case series of 12 patients with severe PANDAS who had failed prior antibiotic and psychiatric therapies showed good response to IVIG given at 1.5 g/kg.⁸³ All patients had significant improvement or complete resolution of their symptoms after months or years of their last IVIG dose.⁸³

Therapeutic plasma apheresis (TPA) has been recommended for patients with severe PANDAS who do not respond to other treatment modalities. A case series of 40 patients with PANDAS describes the use of TPA for patients who were severely ill with violent behavior or who were a danger to themselves or others, severe restrictions of food and/or fluid intake, or minimal or no response to oral steroids or IVIG.⁸⁸ All patients showed some benefit from TPA, with 65% showing a decrease in symptoms at 6 months and 78% at long-term evaluation. The procedure was well-tolerated with minimal adverse effects (bleeding at site of central line insertion in two patients). The authors recommend that IVIG and TPA should be reserved for patients who remain severely symptomatic after less-invasive therapies or if they exhibit life-threatening suicidality, aggressive behaviors, or severe restrictions of food and/or fluid intake.⁸⁸

Experts of the PANDAS Physicians Network (PPN) recommend a multidisciplinary approach for the treatment of patients with PANDAS that should include a combination of antibiotic prophylaxis, targeted symptom treatments, and immunomodulatory therapy. The website www.pandasppn.org provides the clinical guidelines and therapeutic approach recommendations from expert clinicians across the United States.⁸³

Prevention

The pathogenesis of PANDAS has been proposed to be an autoimmune process similar to rheumatic fever and Sydenham chorea.¹⁴⁵ Penicillin is recommended to prevent recurrences of the latter two conditions. Few clinical trials have been performed to determine whether antibiotic prophylaxis to prevent GAS infection can help reduce the neuropsychiatric morbidity seen in PANDAS and prevent future exacerbations. In a placebo-controlled, double-blinded crossover study involving 37 children with PANDAS published in 1999, penicillin failed to prevent streptococcal infections and there were no differences in the severity of OCD and tics between the two phases.⁵⁶ A double-blinded, randomized, controlled trial of 23 children published in 2005 compared penicillin (as “active placebo”) and azithromycin in the prevention of GAS infection and exacerbation of PANDAS. Both penicillin and azithromycin prophylaxis were found to be effective in the prevention of recurrent GAS infections and decreased the neuropsychiatric symptom exacerbations in the PANDAS subgroup.¹⁴⁰ Of note, limitations of this study are a small sample size and lack of inactive placebo group.

Arguments Against PANDAS

Considerable controversy still exists surrounding the topic of PANDAS.^{93,136} Many argue that sufficient evidence is lacking to support PANDAS as a diagnostic entity.¹³² For instance, a prospective longitudinal study comparing PANDAS and non-PANDAS cases of Tourette syndrome and OCD did not show a temporal relation between exacerbation of neuropsychiatric symptoms and a GAS infection in the PANDAS group (a few exacerbations of symptoms were associated with a GAS infection in the control group).⁸⁹ An argument has even been proposed that the initial cases with choreiform movements could represent missed cases of chorea.⁸⁵ The authors in a study showing failure of immune markers to correlate with clinical exacerbations in PANDAS question the autoimmune pathogenesis of the disorder.¹³⁴ Similar concerns were raised by a study that failed to show differences in serum autoantibodies between PANDAS and Tourette syndrome (controls).¹⁰⁰

Further research is needed to establish PANDAS as a clinical entity, to further describe the pathogenesis of the disease, to demonstrate

disease in animal models, and to determine its appropriate treatment and prevention in randomized, double-blinded, placebo-controlled trials.

From PANDAS to PANS

Because the concept of PANDAS has generated much controversy and conflict regarding the scientific evidence to support this hypothesis, many researchers and clinicians have recently proposed to eliminate the diagnosis of PANDAS in favor of a broader diagnostic category.¹³⁵ To address the controversy surrounding PANDAS, experts met at the National Institutes of Health (NIH) in 2010, and modifications to the PANDAS criteria were made to broaden the spectrum of acute-onset OCD and related neuropsychiatric disorders. It was decided that the new syndrome should not exclude cases with postpubertal onset.¹⁴⁷ The term pediatric acute-onset neuropsychiatric syndrome (PANS) was accepted because it would extend the age to at least 18 years (and 21 years by some definitions).¹⁴⁷ The three PANS criteria, as defined by Swedo and colleagues,¹⁴⁷ are:

1. Abrupt, dramatic onset of OCD or severely restricted food intake
2. Concurrent presence of additional neuropsychiatric symptoms (with similarly severe and acute onset) from at least two of the following seven categories:
 - a. Anxiety
 - b. Emotional lability and/or depression
 - c. Irritability, aggression, and/or severely oppositional behaviors
 - d. Behavioral (developmental) regression (Fig. 82.2)
 - e. Deterioration in school performance
 - f. Sensory or motor abnormalities
 - g. Somatic signs and symptoms, including sleep disturbances, enuresis, or urinary frequency
3. Symptoms are not better explained by a known neurologic or medical disorder, such as Sydenham chorea, systemic lupus erythematosus, Tourette disorder, or others

In 2013, a diverse group of clinicians and researchers met at Stanford University for the First PANS Consensus Conference. At this meeting,

a consensus statement proposed recommendations for the diagnostic evaluation of patients presenting with PANS.³²

Most PANS cases are suspected to have a postinfectious etiology, although no organism other than GAS has been consistently associated with the onset of PANS.^{32,51} The most common preceding infection is an upper respiratory infection (e.g., sinusitis, pharyngitis). Organisms most commonly mentioned as suspected etiologies for PANS include *Mycoplasma pneumoniae*, influenza virus, Epstein Barr virus, *Borrelia burgdorferi* (Lyme disease), herpes simplex virus, and varicella zoster virus.^{32,147}

It is important to note that PANS is a “diagnosis of exclusion” and other medical diseases should be ruled out first. Many children can be extremely ill, with extreme compulsions, motor and phonic tics, behavioral regression, and extreme anxiety or aggression. In certain cases, the patients may have visual or auditory hallucinations, and it is important to exclude other diagnoses such as schizophrenia, bipolar disorder, and lupus cerebritis. Laboratory tests recommended for all patients meeting PANS criteria include complete blood cell count with manual differential, erythrocyte sedimentation rate, C-reactive protein, urinalysis with urine culture for those with pyuria, throat culture, ASO titer, and anti-DNAse B.³²

Immunodeficiency workup should also be obtained if there is a history of recurrent infections, infection with an atypical organism, first-degree family member with history of overwhelming and/or fatal infection, or if the patient will receive IVIG therapy. Initial workup should include lymphocyte subsets, quantitative immunoglobulins, and vaccine responses (such as *Streptococcus pneumoniae* and tetanus antibody titers). If workup is abnormal, the patient should be referred to an immunologist. Brain magnetic resonance imaging should be obtained if other conditions are suspected (such as limbic encephalitis, CNS vasculitis) or if the patient has psychosis, altered mental status, or gait abnormalities. Electroencephalogram and lumbar puncture should also be considered in these cases.³²

A study carried out at the University of South Florida involving 43 patients between the ages of 4 and 14 years who met criteria for PANS describes three symptom clusters.¹⁰² The first cluster showed core characteristic PANS symptoms (emotional lability, anxiety, sleep disturbances, deterioration in school, and behavioral regression), the second showed classic streptococcal-related symptoms (ADHD, urinary symptoms, handwriting deterioration, sensory problems, and simple tics), and the third involved cytokine-driven/physiologic symptoms (food restriction, mydriasis, gastrointestinal problems, fatigue, depressive symptoms, psychosis, and complex tics).¹⁰²

Some patients fit all criteria for PANDAS, but since testing for GAS infection may have been done after the window of opportunity to detect GAS passed, these patients end up being classified under PANS.^{51,52} The role of inflammation in the etiology of PANS should be further investigated because there are cases of patients with PANS and overlap with other inflammatory diseases such as autoimmune encephalitis, immunodeficiency, sinusitis, inflammatory pain conditions, or food intolerance. These patients can respond to treatment modalities aimed at controlling the infectious or inflammatory condition, such as antibiotics, immunosuppression, IVIG, or removal of inflammatory foods.⁵²

At the Stanford PANS clinic, 47 youth presenting with PANS symptoms were evaluated.⁵¹ Those with acute onset usually had first-degree family members with autoimmune/inflammatory diseases and psychiatric disorders. GAS was the most common infection identified at onset (21%) and during relapses (74%).⁵¹ Prospective studies are needed to investigate the connections between infections and psychiatric disorders, as well as the connections among infections, autoimmune diseases, and immune dysfunction.⁵¹

Food restriction in PANS has been associated with contamination fears, as well as with fears of vomiting or choking. Clues to distinguish disordered eating of PANS from other eating disorders include acuity of onset, male prevalence, and young age at presentation.¹⁵³ The management for children with PANS presenting with food restriction is different from the presentation for anorexia nervosa or avoidant/restrictive food intake disorder because children with PANS usually respond to treatment with antibiotics or immunomodulatory therapies.¹⁵³

Recommendations for treatment of PANS cases are based on therapies that have been used for patients with PANDAS. Antibiotics used for

FIG. 82.2 Behavioral regression during a symptomatic episode. (A) Drawing produced during an acute exacerbation of obsessive-compulsive disorder and other symptoms of pediatric autoimmune neuropsychiatric disorder associated with streptococcal infections, which appears quite messy and immature. (B) Age-appropriate picture drawn after treatment with intravenous immunoglobulin and symptomatic improvement. (From Swedo SE, Leckman JF, Rose NR. Research Subgroup to Clinical Syndrome: modifying the PANDAS criteria to describe PANS (pediatric acute-onset neuropsychiatric syndrome). *Pediatr Therapeut.* 2012;2[2]:1–8.)

treatment of PANS include amoxicillin, amoxicillin/clavulanic acid, cephalosporins, and azithromycin. A small randomized trial of cefdinir versus placebo for the treatment of recent-onset OCD and/or tics in PANS patients found small improvement in the OCD and tics symptoms in the cefdinir group, but these findings were not statistically significant.¹⁰¹

Just as in the cases for PANDAS who do not respond to other treatment modalities, patients with PANS refractory to other therapies could be considered for treatment with IVIG or TPA.⁵²

GROUP C AND GROUP G STREPTOCOCCAL INFECTIONS

Organisms

The β -hemolytic streptococci include *Streptococcus pyogenes* (GAS), *Streptococcus agalactiae* (group B *Streptococcus*), and groups C, F, and G *Streptococcus*, based on the β -hemolysis they produce on blood agar plates. In addition, *Streptococcus anginosus* group organisms (*S. anginosus*, *S. constellatus*, and *S. intermedius*) may have variable hemolysis, and approximately one-third have group A, C, F, or G antigens.⁶ Depending on their colony size, strains with either the group C or group G Lancefield carbohydrate antigens can be divided into small or large colony-forming strains. The small colony-forming strains (<0.5 mm in diameter) belong to the *S. anginosus* group, which are considered part of the viridans group streptococci. Large colony-forming strains (>0.5 mm) are considered true group C or group G streptococci (GCS and GGS, respectively).²²

Lancefield group carbohydrate antigen and hemolytic reaction have been classically used for the identification of streptococci. However, streptococcal taxonomy has been significantly revised recently because there can be overlap between species. Currently three species of groups C and G have been described that are pathogenic in humans: *S. dysgalactiae*, *S. equi* subsp. *zooepidemicus*, and *S. canis*.²²

GCS are catalase-negative, aerobic, facultatively anaerobic, coprophilic organisms. They are usually β -hemolytic, although all types of hemolysis have been seen with GCS. The group C antigenic determinant in their cell wall is rhamnose-*N*-acetylglactosamine. Four species that possess this antigenic determinant were defined based on their ability to ferment various carbohydrates (*S. equisimilis*, *S. zooepidemicus*, *S. equi*, and *S. dysgalactiae*). Revision of the taxonomy after new research based on genetic studies (such as 16S RNA analysis) has shown that there are actually two GCS species, *S. dysgalactiae* and *S. equi*, each with two subspecies.

GGs typically show β -hemolysis on blood agar plates. They are facultative anaerobes. The group G antigenic determinant in their cell wall is L-rhamnose. The majority of GGS infections in humans are due to *S. dysgalactiae* subsp. *equisimilis*, but a few infections with *S. canis* have been reported.

Some of the same virulent factors found in GAS have been shown to be present in GCS and GGS, such as M protein, streptolysin, hyaluronidase, and C5a peptidase.^{68,72,91,126} The most likely explanation for the overlap in these virulence factors is the horizontal transfer of genes between species.^{120,154} The gene involved is the M-protein gene, which confers resistance to phagocytosis. The proposed mechanism is prevention of complete opsonization of the *Streptococcus* by interfering with the activation of the alternate complement pathway on the bacterial surface.¹²⁰

Epidemiology

GCS and GGS in humans may colonize the skin, oropharynx, gastrointestinal tract, and vagina.⁶ In addition, GCS have been cultured from the umbilicus of asymptomatic newborns and from routine puerperal vaginal samples. Classically these streptococcal groups have been thought to be a rare cause of infection in humans. They are common causes of animal infections, and many humans infected with these streptococci report animal contact. GCS and GGS have been known to cause foodborne outbreaks of pharyngitis.⁶

The classification and nomenclature of GCS and GGS has changed significantly, however, and clinical specimens are rarely identified to the species level by clinical laboratories, making it difficult to know the

true burden of these infections. The first population-based study of the epidemiology and burden of invasive disease due to non-group A or B β -hemolytic streptococci (NABS) in the United States over a 2-year period was published in 2009.²² According to this study, the majority of patients (87%) with invasive disease had underlying comorbid conditions, as has been previously reported.^{68,91} Cardiovascular disease (44%), diabetes mellitus (42%), obesity (30%), and chronic skin disease (30%) were the most common underlying disorders among patients with *S. dysgalactiae* subsp. *equisimilis* bacteremia.^{22,120} *S. dysgalactiae* subsp. *equisimilis* was the most common organism (80%) among patients with invasive disease. The case-fatality rate in bacteremia due to this species is as high as 15% to 18%.¹²⁰ However, the data for individuals younger than 20 years (6% of the patients) were different. Only 23% of the younger patients had underlying conditions, with asthma as the most common comorbidity. Isolates from pediatric patients were most often group F (40%), followed by group G (36%) and group C (24%). One very important finding of this study is that the burden of NABS infection in the United States during the study period was similar to that caused by invasive GAS infection: 3.2 cases per 100,000 population and 2.89 cases per 100,000, respectively.²² A 6-month surveillance study published in Argentina in 2005 reported similar findings that most of the GCS and GGS *S. dysgalactiae* subsp. *equisimilis* infections occurred in adults and that diabetes was frequently seen as an underlying condition.⁹¹

Clinical Manifestations

GCS and GGS may cause invasive disease in infants, older children, and adults. The principal clinical manifestations of these organisms are upper and lower respiratory tract infections, septicemia, pneumonitis, skin and soft tissue infections, septic arthritis, osteomyelitis, meningitis with a parameningeal focus, brain abscess, puerperal and neonatal sepsis, peritonitis, and endocarditis.^{6,8,160}

Pharyngitis caused by GCS and GGS has symptoms similar to those seen with GAS pharyngitis. GCS are a relatively common cause of acute pharyngitis among college students and among adults presenting to the emergency department.^{57,133} Between 1% and 18% of asymptomatic pharyngeal carriers of GCS may be found in temperate climates, with higher percentages in the tropics. Similarly between 1% and 23% of asymptomatic pharyngeal carriers of GGS may occur in temperate climates. In addition, foodborne episodes of pharyngitis have been documented due to GCS and GGS.⁶ These epidemic outbreaks may occur after consumption of contaminated products, such as unpasteurized cow's milk.

There are some studies that report an association with pharyngitis and acute poststreptococcal glomerulonephritis, and an association with acute rheumatic fever with isolation of *S. dysgalactiae* subsp. *equisimilis* from the upper respiratory tract.¹²⁰ Rare neonatal infections due to GGS and GCS have been reported, with symptoms similar to early-onset GBS sepsis.

GCS and GGS have been reported as a rare cause of skin and soft tissue infections. A report reviewing all cases of septic arthritis due to β -hemolytic streptococci at Stanford University Medical Center in California from 1985 through 1996 found that 40% of cases were due to GAS, 30% due to GBS, and 30% due to GGS. No cases due to GCS were reported during that time. Presence of infected prosthetic implants was found in the majority of patients with septic arthritis caused by GGS.¹²⁶ Rare cases of deep soft tissue infection resulting from GGS, such as necrotizing fasciitis, localized pyomyositis, and even myositis with subsequent fatal streptococcal TSS (STSS) have been reported in the literature.¹⁶⁰

STSS typically has been associated with GAS, but recent case reports have shown cases resulting from GCS and GGS infection. Most of the cases have been due to *S. dysgalactiae* subsp. *equisimilis*, but a study from Japan reported the first case of STSS due to *S. equi* subsp. *zooepidemicus*.⁶⁸ Because most clinical isolates of GCS and GGS are β -hemolytic and some isolates are susceptible to bacitracin, some GCS and GGS may have been misidentified as GAS if Lancefield serologic testing was not performed.⁶⁸ Therefore the true rates of these diseases may be underestimated. For the accurate identification of GCS and GGS (such as *S. dysgalactiae* subspecies), molecular diagnostic tests, such as 16S

rRNA sequencing, should be performed.¹⁵⁴ Patients with GAS-related STSS usually are previously healthy, whereas patients with infections due to GCS and GGS, including STSS, usually have underlying conditions such as diabetes mellitus, cardiopulmonary disease, malignancy, collagen disease, liver failure, or renal failure.⁶⁸

Although rare, some cases of bacterial endocarditis may be caused by GCS and GGS infections. The mortality rates for these infections are high, reported as 41% for GCS and 35% for GGS, although the overall mortality rate of infective endocarditis by β -hemolytic streptococci was much lower (12.9%) in a questionnaire study by Baddour and the IDSA's Emerging Infections Network (EIN) members.¹¹

S. anginosus is typically isolated from blood cultures, whereas *S. intermedius* tends to be associated with brain abscesses and *S. constellatus* with intraabdominal abscesses, soft tissue infections, or respiratory tract abscesses.⁹ Children with *S. intermedius* brain abscess have been found to have certain predisposing factors, such as congenital heart disease (most common), sinusitis, otitis media, or dental caries. Infections at other sites caused by *S. intermedius*, such as liver abscess, lung abscess, or bronchiectasis, can also lead to brain abscess.⁹⁷

Treatment

Penicillin remains the treatment of choice for GCS and GGS infections.^{8,123} Penicillin-tolerant strains have been reported in laboratory findings, but the clinical significance is not known.^{8,123} For most GCS and GGS infections, treatment with penicillin G alone is adequate. Other antimicrobial regimens that have been shown to work in vitro include penicillin with gentamicin, other β -lactam agents such as cephalosporins, vancomycin, and vancomycin with rifampin.⁶ Resistance to macrolides, tetracycline, and chloramphenicol has been reported in the literature.^{22,68,91} A few isolates of GCS and GGS *S. dysgalactiae* subsp. *equisimilis* have shown high-level resistance to aminoglycosides.^{22,91}

Guidelines for the treatment of endocarditis due to GCS and GGS have not been established because these infections are infrequent. Usually high-dose penicillin G is recommended for 4 to 6 weeks. Some experts recommend the addition of gentamicin to penicillin for at least the first 2 weeks of therapy.¹¹

Patients may be treated with clindamycin in addition to penicillin in certain cases such as severe cellulitis, necrotizing fasciitis, or STSS, similar to patients with *S. pyogenes* severe infections. For meningitis, similar to endocarditis therapy, an aminoglycoside can be added in addition to penicillin.¹²⁰ For the treatment of a brain abscess (e.g., for *S. intermedius*) a combination of cefotaxime and metronidazole has been recommended.⁹⁷ IVIG in STSS may be considered, but there are not enough data to support its use at this time.

HISTORY

Group B *Streptococcus*, or *Streptococcus agalactiae*, was isolated first by Nocard in 1887²⁶⁶ and for decades was recognized as a cause of bovine mastitis²⁵⁵ but not human infection. Serologic techniques for differentiating β -hemolytic streptococci were developed by Lancefield,²⁰¹ who also described isolation of group B streptococci (GBS) from parturient women in 1935.²⁰³ In that same year, Congdon⁸⁸ included one fatal puerperal case of GBS sepsis and pneumonia in a report of streptococcal infections associated with childbirth. The significance of this organism as a human pathogen was reported first by Fry¹³⁶ in 1938, who described three cases of fatal puerperal sepsis. GBS infections continued to be reported sporadically until the 1960s, when maternal and neonatal infections increasingly were ascribed to this pathogen.^{70,116,170} In the 1970s, GBS emerged as the predominant organism causing bacteremia and meningitis in neonates and young infants.^{13,26,134,173,275} The incidence of infant infection remained stable, with reported attack rates ranging from 0.2 to 5.4 per 1000 live births, until the late 1990s, when maternal intrapartum chemoprophylaxis gained wide acceptance and incidence rates fell.^{78,114,319} Invasive infection also occurs beyond the first 89 days of life in pregnant women, nonpregnant adults with underlying medical conditions, and elderly persons.^{108,120,268}

MICROBIOLOGY

Isolation and Identification

GBS are facultative gram-positive diplococci that grow on a variety of bacteriologic media. Colonies are 3 to 4 mm in diameter, grayish white, flat, and somewhat mucoid. Colonies are surrounded by a narrow zone of β -hemolysis that for some strains is detectable only when the colony is lifted from the agar. Nonhemolytic strains account for 3% to 4% of isolates and can cause human disease.^{13,309} Definitive identification of GBS relies on detection of the group B-specific antigen, a carbohydrate cell wall antigen common to all strains. The standard method, as described by Lancefield,²⁰¹ requires acid treatment of the bacteria to solubilize the carbohydrate group B antigen, followed by capillary precipitation with hyperimmune rabbit serum. Several newer methods using hyperimmune antisera have been developed, but latex agglutination is used widely because of the commercial availability of test kits, the ease of performing the assay, and the specificity of the results when organisms in pure culture are tested.³³¹ Other laboratory methods for presumptive identification include testing for resistance to bacitracin or trimethoprim-sulfamethoxazole, hydrolysis of sodium hippurate broth, failure to hydrolyze bile esculin, production of orange pigment when cultured under certain conditions, and CAMP testing. CAMP is an acronym of the names of the authors (Christie, Atkinson, Munch, Peterson) who first described the production of CAMP factor by GBS in the presence of the β -toxin of *Staphylococcus aureus* that results in synergistic hemolysis on sheep blood agar.⁸⁷ Chromogenic agars that undergo color change in the presence of β -hemolytic colonies can facilitate detection of β -hemolytic strains but will miss the majority of nonhemolytic strains (~4% of isolates).^{345,361} In addition, recently developed rapid techniques for identifying GBS from enrichment broth include DNA probes and nucleic acid amplification tests (NAAT), such as polymerase chain reaction (PCR).³⁶¹

Serologic Classification and Antigenic Structure

GBS possess two carbohydrate cell wall antigens, the group B-specific antigen and type-specific capsular polysaccharide. GBS are classified into serotypes based on type-specific capsular polysaccharides. Nine such polysaccharides are characterized and recognized: Ia, Ib, and II

through VIII. The type-specific polysaccharides of GBS are repeating units of five to seven monosaccharides (glucose, galactose, glucosamine, and *N*-acetylneuraminic acid). All the characterized polysaccharides include an *N*-acetylneuraminic acid (sialic acid) residue, which is important in the pathogenesis of type III human infection and perhaps other types.^{33,326,372} Despite structural relatedness, antibody directed against the capsular polysaccharide of one type does not provide cross-protection against other capsular polysaccharide types.^{202,363,374} A few strains isolated from patients with systemic infection contain type-specific capsular polysaccharide genes by genotypic methods but express low levels of capsule or have modified capsular structures that do not react with hyperimmune sera or monoclonal antibodies to the characterized capsular polysaccharides.²⁹⁷ These strains are called *nontypeable*.

Further differentiation of type Ia strains was based on the presence or absence of a protein antigen known as C, which led to the nomenclature of Ia and Ia/c serotypes. The C protein also is present in many other serotypes except type III strains. Two components make up the C protein: α (trypsin-resistant) found in 70% of non-type III capsular polysaccharide isolates and β (trypsin-sensitive) found in approximately 20% of isolates.^{128,181,234} GBS express additional surface proteins including α -like repetitive proteins (Alp), also referred to as R proteins. R1 and R4 (shown to have an identical gene sequence to Rib) are the major R proteins found on clinical isolates.¹²⁷

Pili, an essential virulence factor in many gram-negative pathogens, were discovered in GBS in 2005²⁰⁸ and play a role in attachment and invasion of host cells²³² and resistance to macrophage phagocytosis.¹⁸⁰ Ongoing analyses of the GBS genome sequenced from multiple pathogenic strains will provide further insights into its antigenic structure, genes contributing to its virulence, and targets for treatment and prevention.^{143,249,349,348}

Extracellular Products

Several bacterial products are elaborated by GBS. Type-specific capsular polysaccharide is released from cells, and the amount elaborated has been correlated with virulence.^{196,383} These soluble polysaccharides inhibit opsonophagocytic killing in vitro, thereby providing a mechanism for the documented increase in virulence.²¹¹ Most strains possess C5a-ase, an enzyme of the serine esterase class that inactivates complement component C5a.¹⁶⁸ Because C5a is a potent chemoattractant for neutrophils, this enzyme helps the bacteria to evade the host immune system by hindering the accumulation of neutrophils at the site of infection. The β -hemolysin elaborated by GBS was characterized in 1980; its role in virulence has been explored through the creation of nonhemolytic and hyperhemolytic mutants.^{238,368} Expression of β -hemolysin correlated with tissue damage in an in vivo arthritis model,²⁹³ activation of neutrophil signaling pathways in brain endothelium leading to development of meningitis,¹⁰⁴ induced neuronal damage,³⁰³ increased virulence in pulmonary infection in rats and rabbits,^{162,265} and directly impaired cardiomyocyte viability and function.¹⁶³ Other bacterial products of GBS, including CAMP factor,^{164,189} lipoteichoic acid,^{161,262,263} pigment,^{223,344} hippuricase,¹³¹ hyaluronidase,²⁴⁷ and nucleases,¹²⁹ have been described, but the contributions of these substances to pathogenesis have not been elucidated.

Antimicrobial Susceptibility

To date, human isolates of GBS have remained uniformly susceptible to penicillin G. However, approximately 10-fold greater concentrations are required for inhibition and killing of GBS than for group A streptococci. Isolates with increasing minimum inhibitory concentration (MIC) to penicillin have been reported, but the significance of this

finding is unclear.^{91,324} GBS also are susceptible to other β -lactam agents, cephalosporins, carbapenems, and vancomycin. However, the first two cases of invasive infection with vancomycin-resistant GBS conferred by insertion of *vanG* elements were described in adults in 2014.^{273,336} The prevalence of resistance to the macrolide-lincosamides (erythromycin, clindamycin, clarithromycin) is increasing since the 1970s from 3.4% to 7.4% of isolates and now up to 48% for erythromycin and 30% for clindamycin.^{57,79,96,307} Resistance is related to the presence of *ermTR*, *ermB*, or *mefA* genes.⁹⁶ Macrolide resistance is highest in type V strains.²¹⁷ Furthermore inducible clindamycin resistance can occur in some strains that appear susceptible in broth susceptibility tests; therefore D-zone testing is important to identify these strains.³⁰⁷ Ninety-five percent of strains are resistant to tetracycline, and resistance to bacitracin, nalidixic acid, trimethoprim-sulfamethoxazole, and metronidazole is uniform.²⁸⁴ Low-level gentamicin resistance is typical, but when gentamicin is combined with either penicillin G or ampicillin, synergistic killing of GBS occurs in vitro and in vivo.^{314,315,341}

As many as 5% to 17% of GBS isolates have been reported to be tolerant to penicillin.^{49,192} Expression of tolerance requires laboratory conditions that promote a greater than 16-fold discrepancy between MICs and minimal bactericidal concentrations. Tolerant strains are characterized in vitro by delayed penicillin killing, similar rates of killing by penicillin whether growth is exponential or stationary, an additive rather than a synergistic response to the combination of penicillin and gentamicin, and deficient autolysis. The clinical significance, if any, of these laboratory-induced properties remains unknown.^{193,194,329}

EPIDEMIOLOGY

Maternal Colonization

Asymptomatic colonization occurs at vaginal, rectal, urethral, and pharyngeal sites in up to one-third of healthy young women.^{54,252} Much effort has been exerted trying to define groups of women at enhanced risk for colonization with GBS. Factors found to be associated with vaginal acquisition include African-American ethnicity, obesity, multiple sex partners, frequent sexual intercourse, male-to-female oral sex, tampon use, and infrequent hand washing.^{54,197,236,252} Women younger than 20 years of age have higher prevalence of colonization.^{14,31} Several studies have found significantly higher colonization rates among African-Americans,^{73,167,252} whereas others found higher rates in Hispanics.³⁰¹ Asians have the lowest colonization rates.^{73,252}

Maternal vaginal or rectal colonization rates during pregnancy vary from 18% to 35% in reported studies.^{21,24,60,99,107,246,283,301} These rates relate to the body sites sampled, microbiologic techniques employed, and the period of gestation in which the cultures are performed. Specimens from the distal portion of the vagina yield GBS more frequently than do specimens from the proximal vagina or cervix.²²⁸ Concomitant sampling of the rectal site results in a 10% to 15% increase in detection over culturing the vaginal site alone.^{21,99} Several investigators have suggested the gastrointestinal tract as the principal reservoir for this organism, and sometimes the rectal site is the only one that yields GBS.^{21,99,171,283} The urinary tract is an important site of infection (asymptomatic bacteriuria) because it is a surrogate for a high density or "heavy" ($>10^5$ colony-forming units per milliliter) genital inoculum and a marker of increased risk for development of early-onset sepsis in neonates.^{228,379} Bacteriuria mandates therapy during pregnancy.³⁶¹

The manner in which swab specimens from the vagina and rectum are processed also is important in accurately assessing colonization.^{76,361} Anogenital culture swabs collected by patients themselves are as accurate as those performed by physicians.^{17,292,351} Swabs can be placed in transport media at environmental temperatures for as long as 96 hours.³⁶¹ Specimens then should be placed in a selective antibiotic-containing enrichment broth medium, rather than on solid media, because solid media fail to detect as many as 50% of GBS carriers.^{28,30} The addition of antibiotics to the broth limits the growth of competing flora, especially gram-negative enteric organisms, and enhances detection.^{24,28,30,242} Todd-Hewitt broth with gentamicin and nalidixic acid (selective broth medium)²⁸ or with colistin and nalidixic acid (Lim broth)²¹⁶ is recommended for detection of GBS colonization.³⁶¹ After overnight incubation, the broth is subcultured onto a 5% sheep blood agar plate and is processed conventionally.

Ninety-two percent of culture-positive women are identified if lower vaginal and rectal cultures are obtained at a single visit with correct laboratory detection methods.¹⁰⁷ The proximity to delivery affects the accuracy of predicting colonization at delivery. Cultures obtained at 35 and 37 weeks' gestation predict colonization at delivery with 87% sensitivity and 96% specificity.^{60,283,382}

Infant Colonization

Colonization and infection in the neonate are associated significantly with the presence of GBS in the maternal genital or gastrointestinal tract at delivery. Vertical transmission from colonized mothers to their infants occurs in 41% to 72% of cases (mean, ~50%).^{7,15,24,62,106,167,246,385} Only 1% to 12% (mean, ~5%) of colonized infants are born to noncolonized mothers.^{15,24,105,246,385} Acquisition is presumed to occur either by the ascending route through ruptured membranes or from contact with the organism in the genital tract during parturition. Heavy maternal inocula in the genital tract ($>10^5$ colony-forming units per milliliter) greatly increase the rates of vertical transmission to neonates and rates of heavy infant colonization.^{10,15,61,171,183} Other factors associated with increased colonization rates in infants include prolonged rupture of membranes (>12 to 18 hours) and vaginal delivery.^{15,167} Maternal intrapartum antibiotic therapy substantially diminishes the vertical transmission of GBS.^{7,61,62,167,360,386} The body sites in neonates most likely to yield GBS are the rectum and throat, a finding reflecting replication of organisms at the respiratory or gastrointestinal tract sites after the ingestion of infected amniotic fluid or genital secretions.¹⁶⁷

Horizontal transmission from nosocomial and community sources has been described.^{1,106,138,267} Infant-to-infant or colonized staff member-to-infant spread may occur through hands of hospital personnel, but epidemics are rare.^{106,267} The rate of community acquisition, presumably by an oral-fecal route, appears to be low, but this has not been investigated thoroughly.^{138,235} Breast milk also has been proposed as a mode of transmission for late-onset infection; most reported cases involved a mother with postpartum mastitis. However, the role of breast milk in infants with late-onset disease, if any, is incompletely understood.^{47,51,199,304}

Incidence of Disease

Before the widespread use of maternal intrapartum chemoprophylaxis to prevent early-onset disease, reported attack rates for GBS disease in infants ranged from 1.8 to 4.0 per 1000 live births.^{268,369,388} Early-onset disease (onset within the first 6 days of life) accounted for approximately 80% of cases.³¹⁹ Late-onset disease (onset from 7 through 89 days of life) rates ranged from 0.3 to 1.8 per 1000 live births.^{100,275} With the 2002 guidelines for universal screening of pregnant women at 35 to 37 weeks' gestation and administration of intrapartum chemoprophylaxis to carriers, the incidence of early-onset disease has decreased to approximately 0.25 cases per 1000 live births, a finding representing a decline of nearly 85% from 1990.^{80,361} However, the incidence of late-onset disease remains unchanged at approximately 0.25 to 0.3 per 1000 live births.^{80,185,361} Approximately 30% of cases of early-onset disease and up to 55% of those of late-onset and late, late-onset disease now occur in preterm infants.^{219,317,322} Late, late-onset GBS disease occurs in infants older than 3 months of age and accounts for 7% to 13% of childhood GBS infections.^{174,319,381} Affected infants typically were born before 34 weeks' gestation or have an underlying immunodeficiency or concomitant infection with human immunodeficiency virus (HIV).^{80,97,174,381} Case fatality rates for all infants with GBS disease have dropped from 46% in the 1970s to 3% to 6% in recent years.^{179,286,361}

GBS infection also is a common finding in pregnant women, with clinical manifestations that include urinary tract infection (usually asymptomatic bacteriuria but also cystitis or pyelonephritis), intraamniotic infection (i.e., chorioamnionitis), postpartum endometritis (often with bacteremia), and puerperal sepsis.^{274,322,387} Occasionally meningitis, septic thrombophlebitis, and other serious complications occur.³⁸⁷ Attack rates of 0.12 per 1000 deliveries have been reported, and 28% of maternal cases are associated with pregnancy loss or birth of an infant with early-onset GBS disease.^{274,387} Nonpregnant women and men account for 68% of invasive GBS disease in adults.¹²⁰ These patients typically are more than 65 years old or have underlying medical conditions,

especially diabetes mellitus, but also malignancy (e.g., breast cancer), HIV infection, liver disease, stroke and other neurologic disorders, decubitus ulcers, and neurogenic bladder.^{108,120,177,268,355}

Risk Factors for Infant Disease

Vertical transmission is a prerequisite for the development of invasive, early-onset infection.^{24,244,275} Evidence suggests that at least 50% of late-onset infections also occur after vertical transmission or from spread within the household.¹⁰⁰ The degree of colonization or inoculum also increases the likelihood of infant disease; heavily colonized mothers are more likely to have infants with invasive infection, and heavily colonized infants are more likely to have either early- or late-onset disease.^{60,100,183,215} Other maternal factors associated with the development of early-onset disease include delivery before 37 weeks' gestation, premature rupture of membranes at any gestation (rupture of membranes more than one hour before onset of labor) or rupture of membranes more than 18 hours before delivery at any gestation, and intrapartum fever.^{13,59,60,100,134,158,275} Women colonized with GBS also have a higher incidence of premature rupture of membranes and preterm labor, a finding suggesting a possible causal relationship between GBS and events leading to preterm birth.^{6,243,248,301} Other maternal factors associated with an increased attack rate of early-onset infection are African-American ethnicity, age younger than 20 years, history of previous fetal loss, history of urinary tract infection with GBS during the current pregnancy, and primiparity.^{321,322} Late-onset disease also is associated with young maternal age and African-American ethnicity.³²² Siblings of infected infants who are the product of a multiple pregnancy (e.g., twins, triplets) have enhanced risk for development of early- and late-onset GBS disease.^{112,276}

Capsular Polysaccharide Types Causing Disease

Reports from the 1970s indicated that the GBS capsular polysaccharide types colonizing pregnant women and neonates were divided fairly evenly among types I, II, and III.^{25,374,375} The current distribution of capsule polysaccharide types in invasive disease from multiple North American studies^{93,153,218,370,387} is shown in Fig. 83.1. Serotypes Ia, followed by III, are the most common cause of early-onset infection, whereas serotype III is the most common cause of late-onset infection. In Europe, type III predominates in both early- and late-onset disease.^{133,352,370} Serotype III is implicated in 80% to 93% of meningitis cases, either as a focus of early-onset disease or as a manifestation of late-onset infection.^{25,26,375} Capsular polysaccharide type V emerged in the 1990s.^{55,73,167,305} Type V causes both early- and late-onset infant disease and is the type most commonly isolated from adults with invasive disease.^{55,305} In Japan, types VI and VIII are the most common isolates from pregnant women.²⁰⁰ Recent studies from the Middle East, Africa, Europe, and North America suggest type IV may be an emerging pathogen.^{98,130,132,346} The least common serotypes causing human disease are types Ib, VI, VII, and VIII.

PATHOGENESIS

For pediatricians, GBS disease predominantly afflicts neonates, a predilection that results from a unique combination of maternal, bacterial, and host factors. Fig. 83.2 shows a simplified flow chart of GBS transmission. First, an organism carried by an asymptotically colonized mother is transmitted vertically to her neonate. Evidence suggests that this transmission may occur in utero shortly before birth or during

FIG. 83.1 Serotype distribution of invasive group B streptococcal strains causing (A) early-onset, (B) late-onset, and (C) late, late-onset disease in infants.^{55,93,153,218,387} NT, Nontypeable.

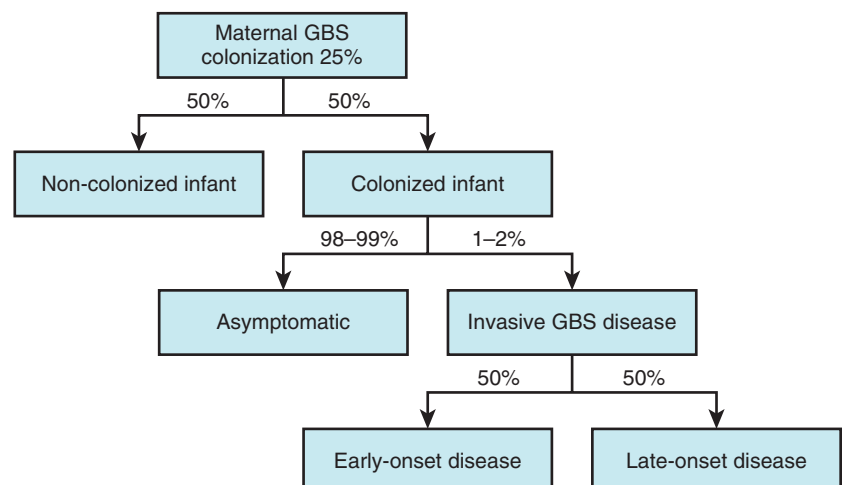

FIG. 83.2 Flow chart of vertical transmission and disease manifestation of group B streptococcal (GBS) disease in the era of intrapartum chemoprophylaxis.

parturition. This continuum in time of acquisition is reflected in the time of onset of symptoms; infected neonates often are ill at or within 12 hours of birth (up to 90% of cases), whereas others may not have evidence of disease for 48 hours or more.^{26,322} The organism successfully colonizes approximately 50% of all infants born to GBS carriers, yet disease develops in only 1% to 2% of these infants.^{13,320} A breach in the delicate interplay of maternal, infant, and bacterial factors allows the organism to invade. Once invasion occurs, a combination of host defenses and therapeutic interventions may halt the progression of disease, or the infant's defenses may fail and the disease may progress and result in tissue damage or death.

Maternal Factors

The bacterial inoculum in the maternal genital tract determines the likelihood that the organism will be transmitted vertically. Infants born to heavily colonized women are more likely to be colonized themselves and are more likely to have early-onset disease.^{10,15,60,100,171,183} Infants delivered before 37 weeks of gestation have an increased risk for development of early-onset disease. Heavy maternal colonization may induce preterm delivery,^{122,244,248,300,302} and disease is more likely to develop in the infant in this setting of high bacterial inoculum and immunologic immaturity. Invasive disease also has been reported in term neonates delivered by elective cesarean section with intact membranes, but this is a rare event.^{13,95,116,190,274}

In addition to bacterial inoculum, another critical maternal factor is the concentration of serum antibody to the capsular type-specific polysaccharide of the colonizing strain of GBS at delivery. Antibodies to the capsular polysaccharide are protective against the homologous serotype in the mouse model of lethal infection; antibody to the group B polysaccharide is not.²⁰⁴ Baker and associates^{29,34} determined that invasive disease with type III GBS occurred primarily in infants born to women with low serum concentrations of antibodies directed against the type III capsular polysaccharide. Several other investigators also reported a correlation between low concentrations of antibody to types Ia, Ib, II, and III capsular polysaccharide in maternal delivery sera and the occurrence of early- and late-onset GBS infant disease.^{145,147} A correlation between antibody concentration and maternal age may explain the epidemiologic association of young maternal age and increased likelihood of neonatal disease.¹³ Animal models have demonstrated that antibodies directed against the α or β determinants of C protein are protective,^{204,253} but definitive human studies are lacking. Invasive disease, but not colonization, elicits immunoglobulin M (IgM) and IgG antibodies to α - and β -C protein in adults.^{269,270} Antibody to other protein determinants in some serotypes has been postulated to be partially protective. Titers of antibody to R protein were found to be higher in maternal serum from mothers colonized with R protein-bearing strains whose infants were healthy than from mothers whose infants were ill; such antibodies were protective in a mouse model against type II, but not type III strains.^{220,221} Presence of maternal antibody to Rib also was associated with protection in neonates against Rib-expressing GBS strains.²⁰⁷

Bacterial Factors

To colonize the genital and gastrointestinal tract or cause disease effectively, organisms must be able to adhere to host tissue. GBS adhere well to many types of epithelium, including vaginal epithelium and chorioamniotic membranes.^{137,227,332,343} Type III strains adhere more avidly to vaginal cells than do other serotypes *in vitro*.⁵⁸ Furthermore invasive strains adhere better to epithelial tissue than do colonizing strains.¹⁵⁹ This capacity to adhere to and possibly invade chorioamniotic cells may explain the association of GBS colonization with preterm labor and premature rupture of membranes. If a breach occurs in the membranes, the bacteria can multiply in amniotic fluid.¹⁶⁰ After transmission and colonization occur, the capacity of the bacteria to adhere to neonatal epithelial cells may allow them to invade and disseminate. The lung, after aspiration of infected maternal fluids, is a frequent initial site of infection in a newborn with early-onset disease. GBS can adhere to and invade respiratory epithelial cell lines.³¹¹ In addition they can invade endothelial cells, which may be a mechanism for some of the pathologic features of disseminated disease.¹⁴¹

Several different factors may confer adherence properties of GBS including bacterial cell wall component lipoteichoic acid²⁶³ or surface proteins.^{69,343} Studies suggest that translocation across epithelial barriers is mediated by α -C protein binding to host cell surface glycosaminoglycan.^{42,82} Several proteins with potential roles in adherence and invasion were identified by detecting upregulation during cell invasion using proteomics and include an undefined surface antigen, penicillin-binding protein 2b, glyceraldehyde-3-phosphate dehydrogenase, and an iron-binding protein.¹⁸² Mouse antisera to these five proteins inhibited binding of GBS to cervical epithelial cells. Translocation also may occur by a paracellular route.^{285,335} Fibrinogen-binding proteins and laminin-binding proteins also contribute to attachment and translocation.²⁰⁵ Adherence to and invasion of the brain microvascular endothelial cells (BMEC) of the blood-brain barrier has been associated with proper anchoring of lipoteichoic acid,¹⁰³ β -hemolysin/cytolysin-induced cytolysis,¹⁰⁴ fibrinogen-binding protein FbsA,³⁴⁷ and pilus proteins.²³² GBS also may attach, invade, and induce a proinflammatory response in human astrocytes that encircle the BMEC and contribute to neonatal meningitis.³³⁹

A well-defined virulence structure of GBS is the capsular polysaccharide. Mouse virulent strains are able to synthesize greater amounts of surface-bound capsular polysaccharide than avirulent strains.^{196,383} An unencapsulated mutant, created by inserting a transposon into the gene regulating capsule expression, has significantly less virulence in neonatal rats than does the wild type III strain.³¹² As with other encapsulated organisms, the capsule is thought to confer virulence primarily by interfering with opsonophagocytosis.²¹¹ *In vitro*, the capsule of type III GBS has been shown to prevent the deposition of C3,²⁴⁰ and the presence of the terminal sialic acid residue on the repeating unit of this polysaccharide is crucial to this interference.¹¹³ Removal of sialic acid residues from the polysaccharide leads to diminished virulence, and a desialylated mutant loses virulence when compared with the parent strain.³⁷³ Furthermore the presence of this sialic acid moiety prevents activation of the alternative complement pathway, the predominant pathway used by the human host when minimal type-specific antibody is present.¹¹³ In addition, when bacteria grow in the presence of human serum, the quantity of sialic acid increases, thereby potentiating its contribution to virulence.²⁸⁸ Opsonization may be affected by cell surface components other than capsular sialic acid. C protein also lends relative resistance to opsonization to strains bearing the antigen.^{181,279} β -Hemolysin/cytolysin enables cytolysis and apoptosis of phagocytes while protecting GBS by the linked carotenoid pigment against oxidative damage.²²³ The toxin-induced damage and inflammation contribute to placental inflammation, disruption of maternal-fetal barriers, and fetal infection in a murine model.²⁹⁹

Sialic acid residues on the capsule may interfere with another component of the immune system. In a serum-free system, the desialylated mutant of type III GBS elicited much larger quantities of leukotriene B₄ from macrophages than did the parent strain.³¹⁰ Leukotriene B₄ is a potent neutrophil chemoattractant, so this effect may result in diminished influx of effector cells. Similarly, C5a-ase may disable C5a, another host product capable of eliciting neutrophil influx. By enhancing phagocytosis and killing of GBS, C5a also has direct stimulatory effects on neutrophils.³⁴² Bacterial elaboration of C5a-ase may affect both the accumulation of neutrophils and the efficiency of neutrophil function. A novel peptide derived from the C-terminal region of 5a was shown to mediate clearance of GBS colonization in a murine model through direct bacterial killing.⁷⁵

Once invasive infection is established, ongoing replication and digestion of bacteria can instigate host inflammatory responses that may be deleterious.²⁰⁵ Neonates recovering from GBS disease have circulating immune complexes for a prolonged period of time, and immune complexes can contribute to end-organ damage.³⁵⁶ Additionally immune complexes containing GBS components elicit inflammatory mediators such as leukotriene B₄ and interleukin-6 (IL-6). The cytokine response to gram-positive pathogens is not delineated as clearly as is that to gram-negative bacteria, partly because of the greater heterogeneity in structure of the latter.⁵⁶ Both group B and type III capsular polysaccharides induce the release of IL-6 from monocytes³³⁵; group B antigen also causes the release of tumor necrosis factor- α (TNF- α).³⁵⁸ As with

other gram-positive pathogens, the cell walls of GBS contain peptidoglycan and lipoteichoic acid. Peptidoglycans from other gram-positive organisms elicit a variety of proinflammatory cytokines such as TNF- α , IL-1, IL-6, and granulocyte colony-stimulating factor.^{101,166,308} Lipoteichoic acid also induces the release of IL-1 β , IL-6, and TNF- α .^{50,191} GBS cell wall components likewise exert similar effects. Elaboration of these cytokines has been implicated in the clinical and hemodynamic effects of sepsis.^{56,371} Specifically blockade of IL-1 activity by administration of an IL-1 receptor antagonist in a piglet model of GBS sepsis ameliorated systemic hypotension and prolonged survival.³⁵⁹

Infant Host Factors

Neonates have several domains of immune dysfunction that affect their ability to mount a sufficient defense against GBS. Neutrophils are the primary effector cell in host defense against extracellular bacterial pathogens, and neutrophils from neonates have many functional abnormalities.²¹² The generation of chemotactic activity in neonatal serum in response to GBS is diminished, as is the release of chemotactic factors by neonatal monocytes.^{11,12,20} Thus the diminished ability of neutrophils to migrate is amplified by a diminished level of chemotactic stimulation. Phagocytosis and bacterial killing also are impaired when opsonic activity is poor, as is the usual pattern in neonates with sepsis.²¹² The neutrophil storage pools of neonates rapidly become depleted during invasive infection, thereby leading to profound neutropenia,⁸⁶ an ominous prognostic indicator.²⁷⁸ These defects in neonatal neutrophils are even more pronounced in infants born prematurely.²¹²

Cells of the monocyte/macrophage lineage also may play a role in host defense against GBS, especially in the lungs, where the alveolar macrophage is the first effector cell to encounter pathogens. Defects in the functions of these cells have been described in neonates, especially preterm infants.⁹⁰ Cord blood monocytes have impaired phagocytosis and killing of GBS.²³⁹ In animal models, oxidative metabolism, bacterial uptake, and migration to the site of infection by neonatal macrophages are diminished in response to GBS.^{241,323,325}

Humoral immunity is compromised in neonates. Both the alternative and classic complement pathways are affected, and preterm neonates are impaired more severely than are term neonates.^{94,110} Both pathways are important in the opsonization of GBS.¹¹⁴ The concentration of type-specific antibody passively acquired from the mother is an important protective factor. Because passive transfer of IgG increases dramatically during the final 8 weeks of pregnancy, premature neonates are again at a disadvantage because they may not receive sufficient amounts of type-specific IgG if they are born before protective levels are transferred.⁸⁵

The pattern of production of cytokines by neonatal immune cells frequently is altered when compared with that of adults. For example, in response to GBS, the level of TNF- α and IL-6 released by neonatal monocytes is increased relative to adults,^{357,358} but levels of IL-8 and leukotriene B₄ are decreased.^{310,316} IL-12 and interferon- γ are associated with improved outcome in an animal model of GBS infection, but lower quantities of these mediators are released by neonatal mononuclear cells.^{188,233} Impairment in the innate recognition systems including Toll-like receptors (TLR) and nucleotide-binding oligomerization domain

(NOD)-like receptors may lead to reduced cytokine production and pathogen clearance.^{89,313} Monocytes from newborns show lower TLR-mediated cytokine production compared to adults.^{90,313} Cytokine networks are important both in the manifestations of sepsis and in the stimulation of an appropriate immune response, so alterations in expression of cytokines may affect the neonate's response to this pathogen both clinically and immunologically.

CLINICAL MANIFESTATIONS

Early-Onset Disease

GBS remains the leading cause of neonatal sepsis since the 1970s, and it accounts for 40% to 50% of early-onset sepsis cases.^{40,53,114,175} The bimodal distribution of GBS infections corresponding to age of neonates and young infants was described first in 1973 and now is divided into two types, termed *early-* and *late-onset disease*.^{26,134} The syndromes of early- and late-onset disease differ in epidemiologic characteristics, pathogenesis, clinical findings, and prognosis. Their major clinical features are detailed in Table 83.1. Early-onset disease is defined as onset of infection in the first 6 days of life, but most neonates (61% to 95%) become ill within the first 24 hours (median, 1 hour).^{59,66,158,322} Premature infants often are ill at birth or within 6 hours of birth and account for 17% to 32% of neonates with early-onset GBS disease.^{22,294,319,322} In very-low-birth-weight infants, GBS has dropped to the second most common cause of early-onset sepsis, after *Escherichia coli*, since the implementation of intrapartum antibiotic chemoprophylaxis.³³⁸

Early-onset disease often occurs in the setting of maternal complications, including labor before 37 weeks' gestation, prolonged rupture of membranes for more than 12 to 18 hours, intrapartum fever greater than 100.4°F, chorioamnionitis, and early postpartum febrile morbidity.^{45,59,60,100,158,369} In one study, neonates born to a mother with one or more of these risk factors were 12.5 times more likely to develop early-onset GBS disease compared with those born to a mother with no risk factors.⁵⁹ A substantial number of term infants can develop GBS disease without definable maternal risk factors except vaginal/rectal colonization.¹¹⁴ In other studies, 65% to 76% of mothers of neonates with early-onset disease had deliveries complicated by at least one of the foregoing identifiable risk factor or was known to be a GBS carrier.^{158,294}

The three most frequent clinical manifestations are bacteremia without a focus, pneumonia, and meningitis.^{13,369,381} The presentation for each may range from shock and respiratory failure at delivery to a healthy infant who has infection detected during evaluation because of maternal risk factors known to increase the risk for development of invasive infection.^{294,369} Respiratory distress, including apnea, grunting respirations, tachypnea, and cyanosis, is the most common initial manifestation in all forms of early-onset GBS disease.^{22,26,134,362,381} Other signs include lethargy, poor feeding, abdominal distention, pallor, jaundice, tachycardia, and hypotension. Fever usually is present in term neonates, but preterm infants often are normothermic or hypothermic.³⁶⁹ Administration of intrapartum antibiotic prophylaxis to the mother does not alter the findings in infants, in whom early-onset disease develops despite administration of intrapartum chemoprophylaxis; most still become clinically ill in the first 24 hours of life.^{40,66}

TABLE 83.1 Features of Group B Streptococcal Disease in Infants

Feature	Early-Onset Disease	Late-Onset Disease	Late, Late-Onset Disease
Age at onset ^{59,66,322}	≤6 days; mean, 8 h; median, 1 h	7–89 days; mean, 36 days; median, 27 days	≥90 days
Infants affected ^{369,322,77,151}	Premature neonates, births after maternal obstetric complications	Term and preterm infants equal	Premature neonates <32 wk gestation, immunodeficiency
Clinical findings ^{114,210}	Acute respiratory distress, apnea, and hypotension common	Fever, irritability, nonspecific signs, occasionally fulminant	Fever, irritability, nonspecific signs
Manifestations ^{13,134,369,381,23,109,185}	Bacteremia (40–55%), pneumonia (30–45%), meningitis (6–15%)	Bacteremia without a focus (55–67%), meningitis (20–35%), osteoarthritis (~5%), cellulitis/adenitis (~2%)	Bacteremia without a focus, focal infections as in late-onset disease
Case-fatality rate ^{78,319,322,369,381,185}	5–15%	2–6%	<5%

Bacteremia without a focus is present in 27% to 87% of neonates with early-onset disease.^{322,369,381} Signs of septicemia, such as respiratory distress and poor perfusion, often are present, especially in neonates born at less than 37 weeks' gestation.³⁶⁹ Bacteremia in healthy-appearing term infants also may develop, and in one series it occurred in 22% of cases.^{173,369,381} These infants probably remained healthy because of early evaluation and institution of empirical antimicrobial therapy.³⁶⁹ Most often, bacteremic infants are mildly ill and have fever and nonspecific signs that should prompt bacteriologic evaluation. Bacteremia also frequently accompanies pneumonia and meningitis.

Radiographic findings of pulmonary involvement include infiltrates suggestive of congenital pneumonia, small pleural effusions, a pattern similar to that of hyaline membrane disease or respiratory distress syndrome, and increased vascular markings as seen in transient tachypnea of the newborn; radiographs also may appear normal despite abnormal pulmonary signs.^{214,224,362} In preterm neonates, the findings frequently are identical to those of respiratory distress syndrome, and at autopsy, hyaline membranes containing bacteria and minimal inflammatory infiltrates have been described.^{2,362}

Meningitis is documented in 6% to 15% of neonates with early-onset disease (Fig. 83.3).^{320,369,377} As a rule, no meningeal signs are present thus underscoring the need to evaluate all neonates with presumed early-onset disease for the possibility of meningeal involvement.^{369,377} Early in the course, the cerebrospinal fluid (CSF) white blood cell count may be normal despite isolation of GBS.¹³ Again respiratory distress is the most frequent clinical finding.^{26,210,369} Seizures rarely are the initial feature but do occur in as many as 50% of affected neonates early in the course of therapy; often these seizures are focal and subtle.²⁶ Postmortem evaluation of infants who die of early-onset GBS meningitis reveals hemorrhage, prominent basilar involvement, and abundant bacteria with relatively sparse inflammation.¹³⁴

Late-Onset Disease

Late-onset disease is defined as infection in infants 7 to 90 days of age, and historically it primarily affected term infants with an unremarkable maternal history and early neonatal course.^{26,100,185} However, one case series suggested that late-onset infection develops in a larger proportion of infants born quite prematurely (<34 weeks' gestation).²¹⁹ Bacteremia

without a focus and meningitis are the two most common manifestations of late-onset disease.^{134,280,381} Osteoarticular infections and cellulitis are additional clinical foci.^{23,109,381} Whereas early-onset disease most frequently occurs acutely with apnea and hypotension, late-onset disease often is manifested by fever, irritability, and other nonspecific signs.¹¹⁴ More fulminant, rapidly progressive cases do occur, however.²⁶

Meningitis is a frequent complication, occurring in 26% to 40% of late-onset disease cases.^{26,185,369,381} GBS accounted for 86% of infant cases under 2 months of age with meningitis in a recent multistate epidemiologic study.³⁵⁰ Late-onset meningitis most typically manifests with fever and lethargy, although respiratory distress, coma, and shock also may occur.²⁶ Classic signs of meningitis, such as a bulging fontanelle and nuchal rigidity, occur more commonly in neonates with late-onset than early-onset meningitis. Subdural effusions develop in as many as 20% of cases, but subdural empyema is a rare occurrence.^{13,26,276} Infants who die of late-onset meningitis have purulent leptomeningitis at postmortem examination.¹³⁴

Late, Late-Onset Disease

Contemporary studies show an increasing incidence of GBS infection in infants older than 3 months of age, defined as late, late-onset disease.^{174,210,319,381} These infections tend to occur in infants who were born extremely prematurely and whose corrected postmenstrual age is less than 3 months.^{174,319,381} Late, late-onset disease also occurs, albeit infrequently, in children co-infected with HIV and those with immunodeficiencies,^{97,174,381} a finding supporting the recommendation that immunodeficiency be considered in any child infected beyond the usual period of risk.⁹⁷ The clinical manifestations in these older infants are similar to those in patients with typical late-onset infection; bacteremia without a focus and meningitis are the most common clinical features.^{97,174} Endocarditis and central venous catheter infection also have been noted.¹⁷⁴

Septic Arthritis and Osteomyelitis

Osteoarthritis occurs in approximately 5% of infants with late-onset infection but appears to be diminishing since implementation of maternal intrapartum prophylaxis.³⁸¹ Among neonates and young infants with osteomyelitis, GBS have been identified as the causal agent in 7% to 38% of cases.^{109,378} The osteoarticular disease usually is more indolent than is the osteomyelitis caused by other etiologic agents in young infants. Diagnosis usually is established after a mean of 9 days of clinical signs at a mean age of 31 days.^{109,114} Decreased motion of the involved extremity, typically the arm, and pain with manipulation are common signs. Warmth and redness are uncommon findings but have been described.¹⁰⁹ Systemic signs and symptoms, including fever, are unusual manifestations.^{109,248}

GBS has a predilection for the proximal humerus.¹⁰⁹ The femur is the second most commonly affected bone. Involvement of more than one bone is an unusual finding.¹⁰⁹ However, involvement of the adjacent joint is described.²⁵⁰ Blood cultures infrequently are positive, unlike neonatal osteomyelitis caused by other etiologic agents. A lytic lesion often is seen on radiographs at first evaluation (Fig. 83.4). This observation suggests that lytic lesions may be a late phenomenon that develops after seeding of the metaphysis during an episode of asymptomatic, early-onset bacteremia several weeks before presentation.¹¹⁴

The mean age at diagnosis in infants who have septic arthritis without osteomyelitis is 20 days. The clinical picture typically is acute, with a mean of 2 days of abnormal findings before diagnosis is established. The lower extremities are involved most often, with the hip joint predominating. Infants typically present with local joint signs in the absence of systemic symptoms.²⁵⁰

Cellulitis/Adenitis

In one case series, 2% of late-onset GBS infections were associated with cellulitis/adenitis syndrome.³⁸¹ Diagnosis is made at a mean age of 5 weeks, with a preponderance of cases in male patients.²³ Typical presentation includes fever, irritability, poor feeding, and swelling of the affected soft tissue area. Enlarged adjacent lymph nodes become palpable within a few days. The most frequent sites of cellulitis are the face and neck,^{23,155,277} with enlarged lymph nodes in the submandibular area. Ipsilateral otitis media was noted in four of five infants with facial or

FIG. 83.3 Head computed tomographic scan at 6 weeks of age from a term infant with early-onset group B streptococcal meningitis shows significant loss of normal brain matter.

FIG. 83.4 Radiograph of the right arm of a 26-day-old infant with a 2-day history of diminished movement of that extremity. A well-defined, lytic lesion is present in the proximal end of the humerus. Necrotic material from this area was debrided surgically and grew group B streptococci on culture. (Courtesy Morven S. Edwards, MD.)

FIG. 83.5 This 3-month-old female infant born after 28 weeks' gestation had fever, lethargy, swelling of the external genitalia, and erythema that extended to the lower part of the abdomen and the thigh. Blood culture grew type Ib/c group B streptococci. (Courtesy Morven S. Edwards, MD.)

submandibular cellulitis in one case series.²³ Less commonly affected areas reported include the genital or inguinal region (Fig. 83.5), the hand, and the prepatellar bursa.^{23,63,376} Aspiration of the affected area of cellulitis often yields GBS, and concomitant bacteremia almost always is present.

Other Manifestations

Nearly every organ has been reported to be a site of GBS infection in young infants. Table 83.2 lists these reported unusual manifestations of early- and late-onset disease.

Recurrent Infections

Second (and rarely third) episodes of GBS infection occur in approximately 1% to 2% of cases after early- and late-onset infection.¹⁴⁸ In a case series from Houston, the mean age at recurrence was 44 days, and the mean duration between the first course of therapy and recurrence was 19 days.¹⁴⁸ Molecular epidemiologic techniques have indicated that most, but not all, of these recurrent infections are caused by the strain implicated in the first episode; this finding suggests that persistent mucosal colonization after treatment of the first episode is followed by invasion of the bloodstream.²⁶¹ Contaminated breast milk also has been implicated as a source of recurrent infection, but this topic is controversial.¹⁹⁹ No specific risk factors are evident in these infants, but most of them are born prematurely.¹⁴⁸

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Laboratory Studies

The diagnosis of GBS infection is confirmed by isolation of this pathogen from a normally sterile body site including blood, CSF, pleural fluid, bone aspirate, joint fluid, or soft tissue. Cultures of the skin, umbilicus, or mucosal membranes do not have clinical significance. Tracheal aspirate cultures that grow GBS indicate neonatal colonization but do not prove pulmonary invasion (pneumonia). Rather isolation of the organism from blood (or in rare circumstances, lung tissue or the pleural space) is required.

Meningitis in early-onset disease is clinically indistinguishable from bacteremia without a focus, and 10% to 38% of neonates with meningitis have negative blood culture results,³⁷⁷ so lumbar puncture is necessary to determine the presence or absence of meningeal involvement. Lumbar punctures also are indicated in patients with a focal site of GBS infection because each results from bacteremia. For example, GBS grew from CSF cultures in 24% of infants with cellulitis/adenitis who underwent lumbar puncture.⁵ One study found that if selected criteria were used instead of routine lumbar punctures, the diagnosis of bacterial meningitis would have been missed or delayed in 17% of infants.³⁷⁷

CSF has had detectable group B antigen in 72% to 89% of neonates with meningitis; serum is much less likely to be positive. The only specimens that should be considered for antigen testing are blood and CSF; urine specimens should not be tested because they are unreliable. Antigen testing should not be used as a substitute for bacterial culture. Their proper use should be limited to the setting of symptomatic infants in whom rapid diagnosis may alter therapy or allow proper tailoring of antibiotic choice: for example, a sick neonate with CSF pleocytosis and previous antibiotic administration. These tests are never useful in infants who appear healthy.

A limited study of real-time PCR to detect DNA in blood of eight neonates with culture-proven GBS sepsis showed positive corresponding results.^{184,187} However, larger prospective studies are required to evaluate sensitivity and specificity.

The white blood cell count of a neonate with proven GBS sepsis may be normal or demonstrate leukopenia, neutropenia, or leukocytosis.^{237,278,362} Manroe and associates²³⁷ found the ratio of absolute immature neutrophils to absolute total neutrophils (I:T index) to be the most reliable index for distinguishing respiratory distress caused by GBS infection from that with a noninfectious origin. Most infected neonates had an elevation greater than 0.20 (91% vs. 4% of uninfected infants). Other markers of inflammation such as C-reactive protein may also rise with acute infection and decrease in response to therapy.^{287,291}

Differential Diagnosis

The signs and symptoms of early-onset GBS disease are clinically indistinguishable from neonatal sepsis caused by other bacterial pathogens such as *E. coli*. The timing is somewhat different, with GBS disease appearing in the first day and *E. coli* with onset on the second or third day of life.¹⁷⁹ The prominence of respiratory signs in early-onset disease may lead to confusion with noninfectious causes of respiratory distress such as transient tachypnea of the newborn, persistent fetal circulation, and respiratory distress syndrome.^{2,22,278,362} Clinical features that suggest GBS infection include a history of prolonged rupture of membranes,

apnea, shock in the first 24 hours of life, a 1-minute Apgar score of 5 or less, and rapid progression of pulmonary disease.^{2,22,362}

The differential diagnosis of late-onset disease depends on the focus of infection. Meningitis in infants of this age also is caused rarely by *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Listeria monocytogenes*, *Haemophilus influenzae* (type b and nontypeable), and more commonly with viruses.³⁵⁰ The findings of osteomyelitis may be subtle; refusal to move the arm may be ascribed to neuromuscular disease or Erb palsy.¹⁰⁹ Careful physical examination usually reveals tenderness over the involved area, and radiographs generally show a lytic defect in the metaphyses.¹⁰⁹ If the organism is isolated from a bone aspirate, the diagnosis is definitive. Finally, as seen in Table 83.2, many unusual manifestations of GBS infection have been described, so this organism should be included in the differential diagnosis of any focal infection occurring in the age group at risk.

TREATMENT

Empirical Treatment

The antimicrobial regimens recommended for the treatment of GBS infection in infants are summarized in Table 83.3. Penicillin G remains the drug of choice because susceptibility is uniform. In the usual circumstance, however, antimicrobial therapy for GBS infection is initiated before culture results are known. Initial empirical therapy for early-onset disease includes ampicillin and gentamicin for the treatment of neonatal pathogens in addition to GBS. Irrespective of gestational age, neonates with suspected meningitis and those whose clinical condition will not permit lumbar puncture should receive high doses of ampicillin (300 mg/kg per day) plus gentamicin.¹³ This combination is more effective than is either ampicillin or penicillin G alone in killing most GBS strains in vitro³¹⁴ and in vivo.³⁴¹ For suspected late-onset disease, the usual initial

therapy includes intravenous ampicillin in combination with cefotaxime or ceftriaxone.⁹ If an infant is receiving empirical vancomycin therapy and GBS meningitis has not been excluded, penicillin G or ampicillin should be added to the regimen because vancomycin is inhibitory rather than bactericidal *in vitro*, and CSF concentrations may not exceed the MIC if a high inoculum of GBS is present.¹¹⁴

Specific Treatment

Once GBS have been identified in cultures of blood, CSF, or other normally sterile body sites and blood and CSF cultures are shown to be sterile, penicillin G alone should be used to complete therapy. Recommendations concerning the optimal dose and duration have varied, but they should be dictated by the focus and severity of the infection (see Table 83.3). Several issues should be considered when selecting the appropriate dose: (1) the usual minimal bactericidal concentration of penicillin for GBS ranges from 0.04 to 0.8 µg/mL,¹⁹² (2) only 10% of penicillin serum levels reach the CSF, (3) the inoculum of GBS in the CSF of infants with meningitis may reach 10⁷ to 10⁸ colony-forming units per milliliter,¹²³ and (4) high doses of penicillin G and ampicillin are safe in neonates.¹¹⁴ To ensure rapid bacterial killing, especially in infants with meningitis, relatively high doses of penicillin are recommended for both early- and late-onset infections.

The infant with meningitis should undergo a second lumbar puncture 24 to 48 hours into therapy to document CSF sterility.¹¹⁴ Infants with continued positive CSF cultures may have very high inoculum, ventriculitis with obstruction, severe infection with cerebritis and vasculitis, subdural empyema, or septic thrombophlebitis, or they may be receiving an insufficient dose of antibiotics; in this circumstance, appropriate studies should be initiated to determine which of these conditions is present. When CSF sterility is verified, penicillin G alone is given for a minimum of 14 days.⁹ Longer treatment is indicated if the course is severe, the infant has ventriculitis, or CSF sterilization is delayed. Another lumbar puncture to evaluate CSF cell count and protein should be considered at the anticipated completion of therapy. Findings of polymorphonuclear cells greater than 30% or protein higher than 200 mg/dL may warrant further diagnostic evaluation and longer duration of therapy.¹¹⁴ In addition, a contrast-enhanced neuroimaging study should be performed near completion of therapy in complicated cases, including infants who have prolonged fever (>5 days), cerebritis, abscess(es), subdural empyema, or venous thrombosis(es). Such complications often correlate with neurologic abnormalities that lead to a poor prognosis for complete central nervous system recovery.^{115,364}

Infants with bacteremia without a focus should receive intravenous therapy for a total of 10 days.⁹ A shorter duration has not been documented to be efficacious, and relapses, although rare, have been reported in these circumstances.^{67,366} Patients with septic arthritis, osteomyelitis, or endocarditis should be treated for the durations summarized in Table 83.3. Oral therapy has no place in the management of infants with invasive GBS disease.^{9,114} Alternative agents such as the third-generation cephalosporins are active against GBS *in vitro*.^{125,217} The clinical efficacy of these agents is unknown, however, and these drugs are not recommended in most circumstances.

Supportive Treatment

The importance of prompt, vigorous, and careful supportive therapy in the successful treatment of infant GBS infections cannot be overemphasized. Neonates with early-onset disease accompanied by pneumonia should be suspected of having early respiratory failure, and ventilatory support should be initiated before the onset of apnea, septic shock, or frank respiratory failure occurs. Persistent metabolic acidosis and delayed capillary refill should prompt treatment for shock. All patients with signs of impending respiratory or circulatory failure or meningitis should be treated in an intensive care unit. When present, hypoxemia, severe anemia, and acidosis should be corrected, and seizures should be controlled with anticonvulsants. In addition, fluid and electrolyte status should be monitored meticulously. Surfactant should be used as per nursery protocol; improved gas exchange is seen in infected premature neonates who receive surfactant, although the response is slower than in patients with respiratory distress syndrome.¹⁶⁵ Finally, if an infant has persistent pulmonary hypertension or if

conventional ventilatory therapy has failed, extracorporeal membrane oxygenation may be considered, if available.

Adjunctive Treatment

Adjunctive treatment of life-threatening GBS disease is aimed at correcting poor host defenses. Such treatments previously studied include intravenous human immunoglobulin, monoclonal antibodies to GBS polysaccharide antigen, leukocyte transfusion, and growth factors such as granulocyte colony-stimulating factor and granulocyte-monocyte colony-stimulating factor for neutropenia.^{71,84,142} The efficacy of these agents has not been established, and, although they may be used occasionally, they should be considered experimental.

Recurrent Infections

In the few infants who experience a recurrence, suppurative foci, HIV infection, or humoral immune deficiency should be excluded or treated. Immunoglobulin levels should be determined to exclude humoral immune deficiency. Although it may be too early to document humoral immune deficiency unequivocally, total IgG usually is significantly lower than would be expected for age in weeks.¹⁴⁸ Susceptibility testing of isolates from the first and recurrent episodes should be determined, if possible, to ensure *in vitro* susceptibility to penicillin. If the reason for the recurrence remains unknown, persistent mucous membrane colonization with GBS is the likely source.²⁶¹ β-lactam antibiotics, even when administered by the parenteral route, do not eradicate GBS colonization reliably.²⁷² Some studies have shown the benefit of rifampin (20 mg/kg per day) to eradicate mucosal GBS colonization when given orally during the last 4 days of parenteral therapy.^{148,254} However, a more recent study showed failure of rifampin to reliably eradicate GBS colonization in infants.¹²⁶

PROGNOSIS

The outcome of GBS disease is related to the severity and site of infection at initial evaluation. Improved outcomes after early-onset infection have resulted from greater awareness among pediatricians and improved obstetric management. Improvements in obstetrics include the use of intrapartum antibiotic prophylaxis in women at risk for delivering an infant with early-onset GBS infection. However, the mortality rate remains substantial at 2% to 8%, especially in neonates born at less than 37 weeks' gestation, in whom the mortality rate often exceeds 20%.^{78,320}

Little information is available on the long-term prognosis of survivors of GBS sepsis without meningitis. In infants with septic shock, the development of periventricular leukomalacia has been reported and associated with neurodevelopmental sequelae.¹¹⁹ However, the frequency of this association is not known.

For infants with early- or late-onset meningitis, 20% to 30% will have permanent severe neurologic impairment such as cortical blindness, bilateral sensorineural hearing loss, cerebral palsy, motor deficits, or significantly delayed development and learning.^{115,154,210,364} Another 25% will have mild to moderate impairment characterized by hydrocephalus requiring ventriculoperitoneal shunt, loss of a digit, seizure disorder controlled by medication, or mildly delayed development and learning. Despite advances in intensive care, a current assessment of term and near-term infants diagnosed with GBS meningitis followed up at 3 to 9 years of age shows that rates of neurologic impairment remain unchanged.^{210,213} Only 51% demonstrate normal age-appropriate development. Features at admission associated with death after hospital discharge or severe impairment include lethargy, respiratory distress, coma or semicoma, bulging fontanel, hypotension requiring pressor support, leukopenia, CSF protein levels greater than 300 mg/dL, CSF glucose lower than 20 mg/dL, and neutropenia.^{39,115,210,213,278} Features at hospital discharge associated with late death or severe impairment include failed hearing screen, abnormal neurologic examination, and abnormal brain imaging at the end of therapy.

To date, the prognosis for infants with osteoarticular or soft tissue infections with GBS has been excellent.^{23,109} However, omission of early surgical intervention for infections that involve either the hip or shoulder joints can result in epiphyseal injury.

PREVENTION

The continuing magnitude and severity of GBS disease and its attendant mortality and morbidity have led to investigations aimed at its prevention. Several general approaches have been proposed: maternal prophylaxis to decrease transmission, infant prophylaxis to decrease colonization, and immunoprophylaxis to increase protection against disease.

Intrapartum Antibiotic Prophylaxis

Maternal Prophylaxis

Epidemiologic studies during the 1980s showed that women with GBS colonization during pregnancy had greater than 25 times likelihood of delivering infants with early-onset disease compared with women with negative prenatal cultures.^{360,361} The idea of giving antibiotic therapy to the mother to prevent vertical transmission to her fetus was suggested first by Franciosi and colleagues.¹³⁴ The first strategy to be evaluated was antenatal treatment of GBS maternal carriers with oral or intramuscular penicillin. This method temporarily suppresses colonization density but does not eradicate colonization or interrupt vertical transmission of GBS to neonates.^{139,150,295}

The next strategy, maternal intrapartum chemoprophylaxis, has been demonstrated to be efficacious in the prevention of vertical transmission of GBS from colonized mothers to their neonates, the development of early-onset disease, and maternal febrile morbidity. Infants are less frequently colonized with GBS if they are born to mothers treated with ampicillin during labor than to mothers not given antibiotics.^{60,61,386} Several controlled trials involving thousands of deliveries indicated that intrapartum penicillin G or ampicillin given intravenously to GBS carriers during labor prevents early-onset disease in neonates.^{62,244,353} Early-onset infection occurred in 0% to 1.1% of infants whose mothers received intrapartum ampicillin compared with 5% to 9% of infants of mothers in the groups not receiving prophylaxis. A large trial involving more than 50,000 live births in Australia showed similar results.¹⁴⁰

In 1996, guidelines supported by the Centers for Disease Control and Prevention (CDC), the American College of Obstetricians and Gynecologists, and the American Academy of Pediatrics recommended a risk-based approach or culture-based approach.³⁶¹ The risk-based approach was based on the presence of one of more of the following: premature labor at less than 37 weeks' gestation, prolonged rupture of membranes (>18 hours), GBS bacteriuria, intrapartum fever (≥100.4°F [38°C]), or delivery of a previous infant with GBS infection. The culture-based approach required intrapartum chemoprophylaxis for all women with positive vaginal and rectal cultures routinely obtained at 35 to 37 weeks' gestation regardless of risk factors. Use of these methods to define women who were candidates for intrapartum chemoprophylaxis led to an approximately 70% decline in the incidence of early-onset GBS disease.^{319,361}

In 2002, a population-based study compared the two approaches and found the culture-based approach to be 50% more effective than

the risk-based approach in preventing early-onset GBS disease.³¹⁸ Sixty-two percent of infants with early-onset disease were born to mothers who were without identifiable risk factors. Therefore revised guidelines published by the CDC in 2002 recommended universal vaginal and rectal screening cultures of all pregnant women between 35 and 37 weeks of gestation, with intrapartum chemoprophylaxis for all women identified as GBS carriers.³¹⁷ The risk-based approach was to be reserved for any women in labor whose colonization status is unknown. Following release of these guidelines, active population surveillance showed that 85% of women were being actively screened, resulting in a 27% further decline in incidence of early-onset infection.³⁶⁰ However, the retrospective cohort study also revealed missed opportunities for screening and chemoprophylaxis for women with unknown colonization status, especially those at risk for preterm delivery. Unpublished data from the CDC showed that antibiotic prophylaxis was 78% effective in preventing early-onset infection in preterm infants.³⁶¹ Thus revised intrapartum chemoprophylaxis guidelines with specific algorithms for women with preterm labor or premature rupture of membranes were released in 2010.³⁶¹ If a woman with unknown colonization status is admitted with signs and symptoms of preterm labor or premature rupture of membranes, a vaginal-rectal swab should be obtained for culture, and intrapartum chemoprophylaxis should be started and continued until delivery. If amniotic membranes are intact, prophylaxis should be discontinued if it is determined that the woman is not in true labor. Women with premature rupture of membranes who are not in labor should continue antibiotics per standard of care if receiving to prolong latency or continue antibiotics for 48 hours if receiving for GBS prophylaxis.

Colonization or bacteriuria during a previous pregnancy is not an indication for intrapartum chemoprophylaxis. Intrapartum chemoprophylaxis also is not indicated for cesarean section performed before onset of labor for a woman with intact amniotic membranes, regardless of GBS colonization status or gestational age. Women with GBS isolated from urine at a concentration of 10⁴ cfu/mL or greater during the current pregnancy should receive intrapartum chemoprophylaxis because these women usually are heavily colonized. Women who previously gave birth to an infant with invasive GBS disease always should receive chemoprophylaxis. Table 83.4 shows the indications and nonindications for intrapartum chemoprophylaxis according to the current guidelines released in 2010.³⁶¹

Optimal culture techniques are discussed earlier in the chapter. Many rapid tests are being studied because they offer the advantage of detecting colonization status in women who present for preterm labor or who have not had prenatal care. These tests include latex agglutination, optical immunoassay, DNA hybridization, enzyme immunoassay, Islam starch medium tests, and PCR.¹⁶⁹ With the exception of PCR, all tests showed poor sensitivity or specificity compared with the standard culture method and are not sufficiently accurate to replace routine culture in decision-making concerning intrapartum antibiotic prophylaxis. A multicenter

TABLE 83.4 Indications and Nonindications for Maternal Intrapartum Prophylaxis to Prevent Early-Onset Group B Streptococcal (GBS) Infection

Intrapartum GBS Prophylaxis Indicated	Intrapartum GBS Prophylaxis Not Indicated
Previous infant with invasive GBS disease	Colonization with GBS during a previous pregnancy
GBS bacteriuria during any trimester of current pregnancy ^a	GBS bacteriuria during previous pregnancy
Positive GBS vaginal-rectal screening culture within preceding 5 weeks ^a	Negative vaginal-rectal screening culture, regardless of intrapartum risk factors
Unknown GBS status at onset of labor and any of the following: <ul style="list-style-type: none">• Delivery at <37 weeks' gestation• Prolong rupture of membranes for ≥18 hours• Intrapartum temperature ≥100.4°F (38°C)^b• Intrapartum nucleic acid amplification test (NAAT) positive for GBS^c	Cesarean delivery performed before onset of labor on a woman with intact amniotic membranes, regardless of GBS colonization status or gestational age

^aIntrapartum chemoprophylaxis is not indicated in this circumstance if a cesarean delivery is performed before onset of labor on a woman with intact membranes.
^bIf amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent active against GBS should replace GBS prophylaxis.
^cGBS NAAT are optional and may not be available in all settings (see text). If intrapartum NAAT is negative for GBS but any other above intrapartum risk factor is present, then intrapartum GBS prophylaxis is indicated.
Modified from Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal disease: Revised guidelines from CDC, 2010. *MMWR Morb Mortal Wkly Rep.* 2010;59:1–32.

study evaluated a real-time PCR assay that gave results in 40 minutes.⁹² Compared with intrapartum culture, the PCR assay had a sensitivity of 94% to 98% and a specificity of 96% to 99%.^{92,117} Nucleic acid amplification tests (NAAT) such as commercially available PCR assays, are an option for intrapartum testing for women who have unknown colonization status at labor onset.³⁶¹ However, NAAT should not replace antenatal culture or risk-based assessment of women with unknown colonization status. NAAT must be performed on samples placed in selective enrichment broths for adequate sensitivity of the assay, thereby lengthening the turnaround time and making it less useful in the real-world setting at this time.

Maternal chemoprophylaxis begins at hospital admission for delivery or at rupture of membranes and consists of intravenous penicillin G (initial dose, 5 million units; subsequent doses, 2.5 to 3 million units every 4 hours until delivery).^{318,361} Although penicillin is preferred because of its narrow spectrum of activity, ampicillin (initial dose, 2 g; subsequent doses, 1 g every 4 hours) can be given as an alternative. For women who are allergic to penicillin, intrapartum chemoprophylaxis must take into account increasing resistance rates to clindamycin and erythromycin.^{57,96} Women at low risk of developing anaphylaxis should be given cefazolin (initial dose, 2 g; subsequent doses, 1 g every 8 hours). Women at high risk of developing anaphylaxis should have susceptibility testing performed on their isolates obtained during screening at 35 to 37 weeks of gestation. Susceptibility testing should include checking for inducible clindamycin resistance. If the isolate is susceptible, clindamycin (900 mg every 8 hours) can be used. Erythromycin is not an acceptable alternative.³⁶¹ If susceptibility testing is not available, the results are not known, or the isolate is resistant to clindamycin, vancomycin (1 g every 12 hours) can be given as the alternative. The efficacy of vancomycin is not known.

Since the widespread adoption of chemoprophylaxis, the incidence of early-onset disease has plummeted but remains stable since 2010.^{319,360,361} Racial disparities in early-onset disease have declined significantly,³¹⁹ but higher incidence of early-onset infection in black infants compared to non-black infants remains a problem. Opportunities to prevent early-onset disease still are missed, however, because of laboratory practices,⁷⁶ hospital or procedural errors in communication of the screening results, failure to administer intrapartum chemoprophylaxis to a mother known to be colonized, or failure to recognize preterm delivery in mothers with unknown colonization status as an indication for prophylaxis.^{294,360} The incidence of late-onset disease remains unaffected by intrapartum chemoprophylaxis.^{185,361}

Management of an infant born to a mother given intrapartum prophylaxis depends on the clinical findings at birth, antibiotic regimen, and the timing of doses administered to the mother (Fig. 83.6). Amniotic fluid levels of penicillin that will kill GBS are not achieved until at least 3 hours after administration of the first dose.⁶⁴ If the infant of any gestational age appears healthy and has a mother who received at least one dose of intrapartum chemoprophylaxis with intravenous penicillin, ampicillin, or cefazolin at least 4 hours before delivery, neither diagnostic evaluation nor empirical antimicrobial therapy is required.³⁶¹ However, to ensure their ongoing stability, such infants should be observed in the hospital for at least 48 hours unless they meet all criteria for early discharge. Keeping the infant hospitalized through day of life 2 has been challenging because the associated expense affects the cost-to-benefit ratio of intrapartum prophylaxis.²⁵⁸ However, an analysis of all live births in the state of Florida for 1992 through 1994 demonstrated a 115% increase in the rate of readmission for GBS infection in infants discharged on day 1 of life; this finding supports the recommendation to observe infants for 48 hours.¹⁴⁶

Neonates with signs of sepsis are evaluated and treated empirically for sepsis. Healthy-appearing neonates who either are born at least 37 weeks' gestation to a mother with an indication for chemoprophylaxis but received inadequate intrapartum chemoprophylaxis should be observed at least 48 hours. An infant born at less than 37 weeks' gestation or following prolonged duration of membrane rupture for greater or equal to 18 hours to a mother with inadequate chemoprophylaxis should undergo limited laboratory evaluation (complete blood count and blood culture) and observation in the hospital for 48 hours without therapy. Adequate intrapartum chemoprophylaxis is defined as at least 4 hours

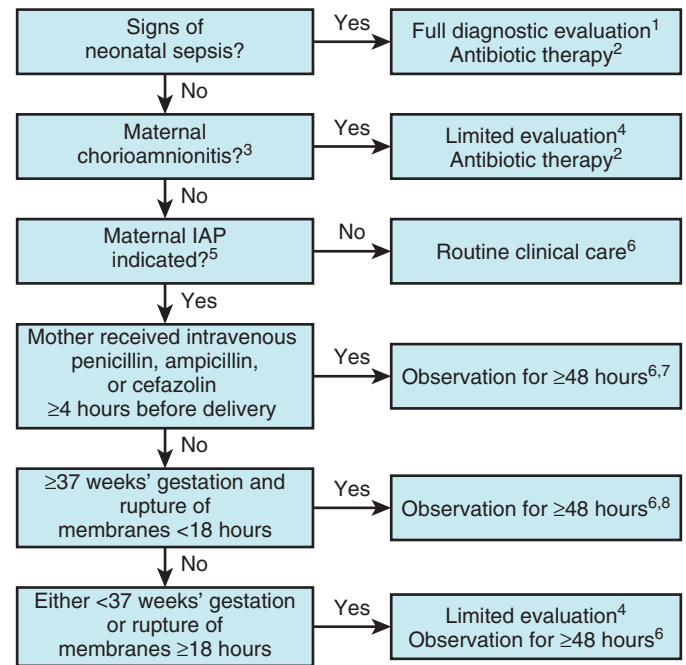

FIG. 83.6 Empirical management of a newborn for secondary prevention of early-onset group B streptococcal infection. 1, Includes complete blood cell count (CBC) and differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed. 2, Antibiotic therapy should be directed toward common causes of neonatal sepsis, including ampicillin for group B *Streptococcus* and coverage for *Escherichia coli* and other gram-negative pathogens, and should take into account local resistance patterns. 3, Consultation with obstetric providers is important to determine the level of clinical suspicion for chorioamnionitis. Chorioamnionitis is diagnosed clinically, and some of the signs are nonspecific. 4, Includes complete CBC and differential and blood culture. 5, See Table 83.4 for indications for maternal intrapartum prophylaxis. 6, If signs of sepsis develop, a full diagnostic evaluation should be conducted and antibiotic therapy initiated. 7, A healthy-appearing infant who was ≥37 weeks' gestation at delivery and whose mother received ≥4 hours of appropriate intrapartum antibiotic prophylaxis (IAP) before delivery may be discharged home after 24 hours if other discharge criteria have been met, a person able to comply fully with instructions for home observation will be present, and access to medical care is readily available. If any one of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until criteria for discharge are achieved. 8, Some experts recommend a CBC with differential at 6 to 12 hours. (Modified from Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal disease: revised guidelines from CDC, 2010. *MMWR Morb Mortal Wkly Rep.* 2010;59:1–32.)

of IV penicillin, ampicillin or cefazolin. All other agents are considered inadequate.³⁶¹ If the subsequent clinical course or the laboratory results suggest infection, full diagnostic evaluation and therapy is initiated.

Concern that widespread use of intrapartum ampicillin use will result in a greater incidence of ampicillin-resistant neonatal infection has been supported by some case series.^{52,187,251} Development of penicillin- or ampicillin-resistant GBS has not been seen.⁸³ In most studies, incidence rates of *E. coli* and other gram-negative pathogens have remained stable.^{4,187,251,306} The rate of ampicillin-resistant *E. coli* infections is increasing in preterm infants. However, rates of ampicillin resistance in term neonates before and after widespread intrapartum chemoprophylaxis are the same.

Infant Chemoprophylaxis

The two controlled trials evaluating neonatal prophylaxis reached contradictory conclusions.^{295,328} In the first trial, more than 16,000 newborns received either intramuscular penicillin G or topical tetracycline (prophylaxis for gonococcal ophthalmia neonatorum) within an hour of birth during alternating weeks.³²⁸ In penicillin-treated newborns,

the incidence of proven early-onset GBS disease was less common, but death rates were similar, and an increase in the number of penicillin-resistant infections in the penicillin group was noted. In the second controlled study, blood cultures were obtained before initiation of penicillin therapy, and rates of GBS bacteremia were similar in the treatment and control groups.²⁹⁵ In this study of nearly 1200 neonates weighing 2000 g or less at birth, intramuscular penicillin (or no treatment) was given in the first hour of life and was continued for 3 days. Rates of GBS bacteremia were similar in the treatment and control groups. Penicillin prophylaxis probably was ineffective because almost 90% of neonates with early-onset GBS disease were bacteremic immediately after birth. The results of the second study are supported by numerous observations, thus indicating that early-onset disease often begins in utero.^{61,275,321} Infant chemoprophylaxis currently is not recommended.³⁶¹

Immunoprophylaxis

Although efforts to improve implementation of intrapartum chemoprophylaxis are ongoing, the most promising and potentially lasting method for prevention of both early- and late-onset infant infections is immunoprophylaxis (i.e., maternal GBS vaccination). This approach remains investigational, and several reviews have summarized the rationale.^{32,111,157,230} It is based on the observation that immunity to GBS correlates with antibody directed against the type-specific capsular polysaccharides of these organisms. These IgG class antibodies and complement promote opsonization, phagocytosis, and bacterial killing of GBS and protect animals against lethal challenge.^{271,372} Thus provision of protective levels of type-specific immunity to the infant could be achieved through active immunization of the mother. A study immunizing women with a III capsular polysaccharide-tetanus toxoid conjugate reported a 95% immune response, with persistence of opsonophagocytic antibodies at 2 months of age in 100% of infants born to maternal responders.³⁸ Other studies immunizing nonpregnant adults with purified capsular polysaccharide-tetanus toxoid conjugate vaccines showed the safety and immunogenicity of these vaccines.^{35–37} A recent phase 2, randomized, observer-blind, multicenter study of a trivalent CPS conjugate vaccine at 24 to 35 weeks' gestation resulted in placental antibody transfer ratios of 66% to 79%.¹⁰² Infant antibody concentrations remained at 22% to 25% of birth levels for at least 3 months after birth. Clinical trials are planned with multivalent CPS conjugate vaccines with CRM197 as the carrier protein and a protein vaccine made from the N-terminal domains of the Rib and α -C surface proteins of GBS.¹⁵⁷

Availability of the complete genome sequences for GBS has led to the discovery of many potential surface proteins and secreted proteins that can be expressed in recombinant form and used for production of antibodies.^{231,349} A set of proteins shared by the disease-causing serotypes theoretically can be used in combination to create a vaccine capable of providing protection against multiple serotypes. GBS pili with at least one of the pilus islands present in all sequenced GBS genomes may be included in a future vaccine.^{68,180}

Because most pregnant women in the United States (estimated at 85–90%) have nonprotective levels of these antibodies in their sera at delivery, active immunization of women of childbearing age before or during pregnancy would optimize the strategy to induce high maternal antibody levels. Human studies have demonstrated efficient antibody transfer to the neonate, as discussed earlier.^{38,102} Transfer of high levels of maternal antibody would provide protection of the neonates from early- and late-onset GBS disease.^{27,186} In addition, immunization also would offer protection for the mother against preterm deliveries and fetal loss caused by GBS infection. Finally vaccination of elderly or nonpregnant adults with defined medical conditions could reduce the disease burden significantly. Because immunoprophylaxis most likely is the most cost-effective and beneficial prevention strategy for GBS

disease,^{156,259,330} it should be promoted by physicians, public health officials, parents, pharmaceutical manufacturers, and legislators.

84A ■ Enterococcal Infections

J. Chase McNeil

ENTEROCOCCAL INFECTIONS

The enterococci are gram-positive ovoid bacteria that are related closely to the streptococci but are phylogenetically distinct and make up the genus *Enterococcus*. These organisms are found in normal bowel flora of humans and many animals and commonly are isolated from environmental sources. Enterococci generally are considered to be of low virulence but have been known to cause human infection since 1899 (reviewed by Murray²⁰⁶). Although these ubiquitous bacteria are important causes of both nosocomial and community-acquired infection in adults* and children,[†] the role of *Enterococcus* spp. as a pathogen (or co-pathogen) in certain clinical settings, particularly intraabdominal and pelvic infections, often remains unclear.

Enterococci are intrinsically resistant to many antimicrobial agents (including the cephalosporins, oxacillin, clindamycin, and aminoglycosides). Since the emergence of high-level aminoglycoside resistance in *Enterococcus* spp. more than 40 years ago,¹⁹³ increasing percentages of these organisms have acquired clinically significant resistance to β -lactam antibiotics, vancomycin and other glycopeptides, and aminoglycosides. Vancomycin-resistant enterococcal (VRE) infections, especially those caused by vancomycin-resistant *Enterococcus faecium* (VREF), are of particular concern because VREF isolates frequently are resistant to other bactericidal antimicrobial agents.^{5,205,207,259} The dramatic increase in nosocomial VRE infections^{4,78,204,219} has resulted in failure of antimicrobial therapy¹⁵⁶ and has inspired comparisons with the preantibiotic period⁶ and even speculation about a “postantimicrobial era.”⁵⁶ Fortunately new classes of antimicrobials active against most VRE isolates have become available recently, but pediatric experience with these agents is limited, and enterococci resistant to these agents already have been detected (see later discussion). Concern about the continued nosocomial spread of VRE isolates and the documented transfer of vancomycin resistance determinants to *Staphylococcus aureus*^{36,38,291,303} led to the development of stringent hospital infection control guidelines designed to interrupt the spread of vancomycin-resistant organisms.²¹⁴ Although the impact of VRE infections in children has been less dramatic, many pediatric centers report infections caused by these organisms.[‡]

MICROBIOLOGY

The genus *Enterococcus* consists of gram-positive cocci that are catalase-negative and occur singly, in pairs, and in short chains. Morphologically enterococci are indistinguishable from streptococci and traditionally were classified as members of the genus *Streptococcus*. Sherman's early classification scheme²⁶⁹ divided the streptococci into four groups: pyogenic, viridans, lactic, and enterococcal. By the Lancefield criteria, enterococci were classified as group D streptococci, along with the “nonenterococcal” *Streptococcus bovis* group. However, genetic evidence

has indicated that the enterococci are sufficiently different from the streptococci to merit establishment of a separate genus.⁸⁴

Fig. 84A.1 is a scheme for the differentiation of enterococci from other gram-positive cocci. Catalase-negative gram-positive cocci that have been isolated from human sources include the streptococci, the enterococci, *Lactococcus* spp., *Leuconostoc* spp., *Pediococcus* spp., and *Gemella* spp. Most enterococci produce no (γ) or partial (α) hemolysis on blood agar; differentiation between enterococci and certain α -hemolytic or nonhemolytic streptococci and other nonstreptococcal gram-positive cocci may require a series of biochemical tests.^{82,84} Clinical laboratories may identify an organism presumptively on a primary isolation plate as an enterococcus based on colony morphology, Gram stain, and the pyrrolidonyl arylamidase (PYR) test. Most enterococci produce PYR, as do *Streptococcus pyogenes* and nutritionally variant streptococci (*Abiotrophia*), but not other streptococci. The PYR test is particularly useful for differentiating enterococci from group D streptococci and *Leuconostoc* spp. (see Fig. 84A.1). *S. pyogenes* and *Abiotrophia* spp. are distinguished easily from enterococci by colony morphology, hemolysis, and special growth requirements.

Enterococci are able to hydrolyze esculin in the presence of 40% bile salts; of the true streptococci, only group D streptococci (*S. bovis* group) and approximately 5% to 10% of viridans streptococci share this characteristic.⁸⁴ Enterococci are facultatively anaerobic and grow under harsh conditions that inhibit the growth of streptococci; growth in 6.5% sodium chloride at 45°C (113°F) is a useful confirmatory test. Enterococci produce leucine aminopeptidase, as do streptococci, lactococci, pediococci, and some *Gemella* strains. The presence of group D streptococcal antigen is of limited value because the *S. bovis* group, most pediococci, and half of the clinical *Leuconostoc* spp. isolates share this antigen.⁸⁴

Occasional clinical isolates of *Leuconostoc* spp., *Pediococcus* spp., and *Lactococcus* spp. may be difficult to distinguish from the enterococci. Some strains of *Leuconostoc* spp. and *Pediococcus* spp. may grow in 6.5% NaCl at 45°C, but they are PYR negative. Lactococci are PYR-positive, and some isolates will grow in 6.5% NaCl; however, most lactococci fail to grow (or grow very slowly) at 45°C. Consequently definitive confirmation of an organism as an enterococcus may require complete identification to the species level. Molecular techniques allow rapid, reliable identification and speciation of enterococci^{62,72,76} but usually are available only in the research setting.

The genus *Enterococcus* now includes at least 14 “typical” species and three additional “atypical” species (the latter are PYR negative and grow very slowly in the presence of 6.5% NaCl) (Box 84A.1). However, most human clinical isolates are either *Enterococcus faecalis* (50–90%) or *E. faecium* (5–37%), although clusters of human infection caused by *E. raffinosus*,⁴⁵ *E. casseliflavus*,²¹² *E. avium*,²²⁶ and *E. durans*²⁶³ and occasional human infections attributable to *E. gallinarum*, *E. mundtii*, and *E. flavescens* have been reported.⁸³ Even though *E. faecalis* and *E. faecium* continue to account for most clinical isolates, the percentage of *E. faecium* isolates has been increasing, and relatively more “other” (i.e., non-*faecalis* and non-*faecium*) enterococci are being identified by clinical laboratories.^{139,141,170}

Speciation of enterococci has been useful primarily for epidemiologic purposes, but distinction between the more antibiotic-susceptible *E. faecalis* and the more antibiotic-resistant (see later discussion) *E. faecium* may be helpful in selecting optimal therapy for endocarditis and other

serious enterococcal infections. A panel of biologic tests can differentiate these two common enterococcal species readily.^{84,147,206} Most *E. faecalis* isolates (unlike those of *E. faecium*) grow in the presence of 0.04% tellurite, reduce tetrazolium to formazan, and produce acid from sorbitol and glycerol.

A variety of molecular techniques are available to assist in the identification of enterococci and determination of the relatedness of enterococcal isolates.^{51,52,71,76,198,308} These molecular techniques have been particularly valuable in investigations of possible nosocomial transmission of multiresistant enterococci.

EPIDEMIOLOGY

Enterococci are normal flora of the gastrointestinal tract of most humans and have been found in as many as 97% of fecal samples from adults in Europe, Asia, and North America.²⁰⁶ Approximately half of newborn infants become colonized with enterococci by the time they are 1 week of age.²¹⁵ Enterococci are isolated less commonly (<20% of specimens) from other sites, including the vagina, oral cavity, and skin. These organisms also are common inhabitants of the bowel flora of many animals and frequently are present in soil, water, and food. Enterococci are hardy organisms and may persist for long periods on environmental surfaces, thereby contributing to potential nosocomial spread of these bacteria.

Human infection caused by enterococci was reported before the beginning of the 20th century, but the initial reports included patients with infections that seldom are associated with enterococci today: enteritis, meningitis, and appendicitis.²⁰⁶ The ubiquitous presence of enterococci in fecal samples led to the mistaken impression that these organisms cause enteritis and food poisoning. Enterococci are isolated commonly as part of mixed flora in intraabdominal and pelvic infections, but the contribution of these organisms to the pathogenesis of such infections remains unclear.^{102,213} However, enterococci were identified as pathogens causing urinary tract infection and endocarditis as early as 1906,⁵ with later confirmation by many studies. Subsequently, enterococci have been documented to cause invasive infection in neonates,^{9,71,98,115,151,234} patients with malignancies,^{106,107,153,197,217,268} recipients of bone marrow and solid organ transplants,^{15,88,91,145,149,189,225,257} burn victims,¹⁵⁸ patients with indwelling catheters,^{15,63,195,204,206,219} and other immunosuppressed or debilitated patients.^{39,168,173,185,189,227,242}

In general, enterococcal infections occur less frequently in children (outside the neonatal period) than in adults, and enterococci are less common causes of pediatric (vs. adult) urinary tract infection³¹² and endocarditis.²⁷⁹ There are relatively fewer series of pediatric enterococcal infection published than those in adults.^{22,25,30,51,63,90,106,114,177,246} Much of the published experience with enterococcal infection in children focuses on the neonatal period,^{59,71,98,115,173,238} and some evidence suggests that late-onset (but not early-onset) neonatal enterococcal infection may be increasing in frequency.^{51,71} In one recent series, *E. faecalis* was the third most common organism to cause late-onset sepsis in neonates.²¹

Enterococci are important nosocomial agents, and they rank as either the second or third most common hospital-acquired pathogens in this country.^{5,37,78,142,202,244,258,314,315} Evidence of nosocomial spread of enterococci is relatively recent. Initially, all enterococci isolated from hospitalized patients were thought to have originated from the patient's endogenous bowel flora. However, the emergence of multiantibiotic-resistant enterococci prompted the performance of careful epidemiologic studies that documented the nosocomial spread of these organisms.^{5,37,78,142,202,244,258,314,315} Many groups have reported that VRE and other enterococcal isolates may persist for long periods in the environment and may be spread either by direct patient-to-patient contact via the hands of colonized health care personnel²³⁸ or from contaminated beds or other hospital material or contaminated patient equipment, including thermometers.^{5,26,146,164,195}

The growing problem of nosocomial infection by VRE organisms is multifactorial; the diversity of isolates found in many hospitals indicates that resistant organisms may be introduced via multiple sources.^{50,76,98,198,204,244,269} Consequently outbreaks of VRE infection in institutions may be caused by single or multiple clones, although the first recognized outbreak of VRE infection or colonization in a hospital usually is associated with a single clone.^{40,99}

Distinguishing risk factors for VRE colonization from those for invasive disease caused by these organisms has often not been possible, and certain factors probably increase the risk for both colonization and development of infection caused by VRE organisms. Major risk factors for VRE colonization or the development of infection, or for both, appear to be the severity of the underlying illness or immunosuppression; the proximity to patients colonized with VRE organisms (e.g., admission to an intensive care unit [ICU] or a transplant unit); receipt of a bone marrow or solid organ (especially liver) transplant; increasing length of hospital stay; recent cardiothoracic or abdominal surgery; the presence of indwelling central venous or urinary catheters; and previous treatment with vancomycin, broad-spectrum antibiotics (particularly those lacking appreciable antienterococcal activity, such as the third-generation cephalosporins), or agents with broad antianaerobic activity.^{17,18,52,109,238,242,244,246,276,315} Among neonates specifically, VRE colonization has been especially associated with the use of broad-spectrum antibiotics.¹²⁹ Patients infected with human immunodeficiency virus (HIV) also appear to be at higher risk for the development of VRE bacteremia.¹⁵ Factors contributing to nosocomial spread of these organisms probably differ from those responsible for the gradual overall increase in resistant strains.²⁴²

Since the first report of a vancomycin-resistant isolate in 1988,¹⁶⁰ infection and colonization with VRE bacteria in the United States have been observed primarily in the ICUs of large teaching hospitals.^{37,205,207} For example, data reported to the National Nosocomial Infection Surveillance (NNIS) system of the Centers for Disease Control and Prevention (CDC) from January 1989 through March 1993 revealed no vancomycin resistance in hospitals with fewer than 200 beds, a resistance rate of 1.8% in hospitals with 200 to 500 beds, and a rate of 3.6% in hospitals with more than 500 beds.³⁷ A 1995 report from the multicenter *Enterococcus* Study Group analyzed 1936 isolates collected from 97 laboratories in 47 states during the last quarter of 1992 and generally confirmed the findings of the NNIS survey.¹³⁹ However, VRE infections are not limited to ICUs. A 1999 report from the Surveillance and Control of Pathogens of Epidemiologic Importance (SCOPE) group's ongoing surveillance of nosocomial bloodstream infections in 49 US hospitals revealed no overall differences in rates of vancomycin resistance in enterococci isolated from patients located in critical care versus hospital ward settings.⁷⁸ In a multicenter surveillance study in Canada, a dramatic increase was seen in the incidence of VRE bacteremia

increasing from less than 0.01 per 1000 hospital admissions in 2006 to more than 0.08 per 1000 in 2009.¹⁸¹ In this study much of this shift was associated with the emergence of new sequence types of VRE. Fortunately VRE infections have occurred much less frequently in children than in adults, and overall rates of vancomycin resistance in enterococci isolated from children's hospitals remain very low. That being said, many pediatric centers, however, have reported VRE infections.^{22,25,58,71,98,151,173,183,238,273} In a large survey of European bloodstream isolates, a similar proportion of *E. faecium* isolates from children were resistant to vancomycin as was seen among isolates from adults.¹⁶

In the United States, VRE isolates generally have not been detected in environmental sources or in patients who have not had exposure to hospitals,^{205,206} with rare exceptions.⁴⁰ VRE was only isolated from one of 1,813 stool specimens in healthy children in the community setting.¹¹³ However, the ecology of VRE organisms in Europe differs: they have been detected in the feces of nonhospitalized patients and healthy volunteers in several European studies, with rates of VRE colonization as high as 28% in adults living in some parts of Belgium.^{205,206} The more widespread occurrence of VRE strains in Europe probably was related to the use of oral glycopeptides such as avoparcin in animal feed and the oral administration of bacterial preparations (possibly contaminated with resistant enterococci) to humans and animals for therapeutic purposes.^{203,205,206}

Initial reports of VRE organisms in the United States were clustered in the northeast region, particularly New York, Maryland, and Pennsylvania,³⁷ and geographic differences in rates of VRE colonization and infection persist. However, subsequent reports indicate that VRE strains are found in most parts of the United States^{138,170} and that rates of vancomycin resistance among enterococci isolated from patients in this country generally are higher than those found in isolates from Canada, Western Europe, or Latin America.^{137,140,170} The reasons for these geographic differences remain unclear, but the high rates of resistance in the United States may be related to the increased use of vancomycin in this country during the past 3 decades.¹⁵⁰

Interestingly, new evidence has emerged regarding the origin of drug-resistant *E. faecium*. Using whole genome sequencing, Lebreton et al. were able to demonstrate that a dominant multidrug resistant strain of *E. faecium* evolved from a population that included animal strains and not from human commensal strains. This diversion from animal strains occurred approximately 75 years ago at the time of the widespread introduction of antibiotics.¹⁵⁹ Other investigators have noted similar antibiotic resistance determinants in processed meat products and human clinical isolates despite genomic diversity between these sources, suggesting horizontal transfer of antibiotic resistance from animal to human strains of enterococci.²⁰⁸

PATHOGENESIS AND VIRULENCE

Enterococci are organisms of low virulence, and their ubiquitous presence in the human gastrointestinal tract probably has contributed to both the spurious association of these organisms with some illnesses (e.g., enteritis) and the failure to recognize other situations in which enterococci are true pathogens (e.g., immunosuppressed and debilitated patients and neonates). When contrasted with organisms such as *S. pyogenes* and *S. aureus*, enterococci are much less virulent in animal models of infection,^{133,194} but they are capable of causing disease at a higher inoculum.

Enterococci rarely cause primary cellulitis or abscesses, although these organisms are isolated frequently as components of polymicrobial wound infections and intraabdominal and pelvic infections. The contribution of enterococci to the pathogenesis of these polymicrobial infections remains uncertain.^{102,213} In animal models, synergy between enterococci and a variety of other organisms (particularly anaerobes) can be demonstrated, but enterococci injected alone have little propensity to cause either peritonitis or subcutaneous infection.^{133,134,206,221} Many clinical trials have concluded that provision of antienterococcal therapy generally is not necessary to effect a cure of human intraabdominal and pelvic infections, even though *Enterococcus* frequently (14–33% of cases) is isolated from primary peritoneal cultures.¹⁰²

Enterococci are an important cause of urinary tract infections in adults (particularly in elderly men, patients with structural abnormalities of the urinary tract, and those with indwelling urinary catheters), but

they are associated less frequently with urinary tract infections in children.^{9,312} Enterococci also are important but less frequent (than in adults) causes of bacterial endocarditis in children.^{186,280}

Adherence of bacteria to tissue is a necessary first step in the pathogenesis of both urinary tract infection and endocarditis, and evidence suggests that pathogenic enterococci produce factors that mediate adherence to urinary epithelial cells and endocardial tissue.^{133,134} Enterococcal adhesins include an enterococcal surface protein known as aggregation substance^{47,154} and surface carbohydrates. Lipoteichoic acid, an important adhesin for *S. pyogenes*, does not appear to mediate adherence of enterococci,²⁷⁵ but it may trigger the host inflammatory response to these organisms.²⁸⁷ The innate immune response to enterococci is poorly understood, although one report has implicated the intracellular sensor nod2 in mediating the host inflammatory response to these organisms.¹⁴⁸ Recent studies have implicated an enterococcal surface protein, Esp, in biofilm formation by *E. faecalis*.^{34,290} Enterococcal secreted antigen A (SagA) as well as extracellular DNA appear to be critical components of biofilm formation among clade A1 *E. faecium*, the dominant hospital-acquired strain.²²³ In addition, many virulent *E. faecalis* isolates express a cytolysin in the presence of target cells.^{55,60}

Nosocomial enterococcal bacteremia in adults frequently is associated with urinary tract and wound infections, but catheter-related bacteremia is of increasing importance. Enterococcal bacteremia without a source occurs relatively more commonly in children,^{25,242} although Bonadio²² reported that many children with enterococcal bacteremia had an identifiable focus of infection. Enterococcal bacteremia occurs more frequently in patients with severe underlying disease and may be life threatening. However, the precise contribution of enterococcal bacteremia to morbidity and mortality in the severely ill remains unclear in individual patients. Adult ICU patients with enterococcal bacteremia have a very high mortality rate,¹⁰⁴ and some early studies suggested that isolation of *Enterococcus* from blood merely served to identify a very high-risk group of patients.²⁰⁶ In several studies, clearance of VRE organisms from blood was not associated with a reduced mortality rate in this high-risk population. In other studies, spontaneous resolution of VRE bacteremia has been reported, thus suggesting that transient VRE bacteremia or pseudobacteremia (or both) may occur.²⁹⁷ However, a series of subsequent studies clearly associated vancomycin resistance with an increased risk for mortality in certain patients and has demonstrated that effective antienterococcal therapy reduces the overall mortality rate in patients with VRE bacteremia.^{69,70,77,123,205,227} Taken together, these findings indicate that at least a subset of high-risk patients with VRE bacteremia are at risk for the development of significant morbidity and mortality directly related to the infection.

CLINICAL MANIFESTATIONS

Enterococcal infections generally occur less frequently in children than in adults, but *Enterococcus* is a relatively frequent cause of neonatal infections.⁷¹ The types of infections caused by enterococci in children are similar to those in adults,^{22,25,63,114,242} although enterococcal bacteremia may be associated with fewer sequelae in children.⁶³ In children, as well as in adults, enterococci have become increasingly important nosocomial pathogens.* They are important causes of endocarditis, urinary tract infection, and bacteremia (particularly catheter-related bacteremia) in pediatric patients, and these organisms commonly are isolated as components of polymicrobial wound, intraabdominal, and pelvic infections in children.^{22,25,195,206} Meningitis²⁸³ and septic arthritis²³⁵ are rare manifestations of enterococcal infection. Enterococci are also important causes of peritonitis in children being treated with peritoneal dialysis.²⁸³ Respiratory tract infections caused by enterococci are rarely recognized, although many neonates with enterococcal infection have pulmonary symptoms.⁷¹

Urinary Tract Infection

Urinary tract infections are the most common enterococcal infections in adults,^{5,195} and enterococci are important urinary pathogens in children.^{8,64,177} Most enterococcal urinary tract infections occur in elderly

men after they have undergone urinary catheterization, instrumentation, or both.^{86,200} Enterococci are infrequent causes of cystitis and pyelonephritis in otherwise healthy children, infants, and neonates^{8,312} and are infrequent causes of urinary tract infection in young women.²⁰⁶ Notably, however, some centers are reporting an increasing incidence of both community-acquired and nosocomial urinary tract infection caused by enterococci.⁸⁶ Cantey et al.³³ reported that *E. faecalis* was the second most common cause of urinary tract infection in otherwise healthy febrile infants younger than 60 days in Dallas, Texas, accounting for 16 of 171 cases (9.4%). Investigators from Israel found that enterococci were responsible for 5.6% of community-acquired urinary tract infections.¹⁷⁷

Most enterococcal urinary tract infections in children^{8,64,166} and adults^{86,94} are nosocomial. Risk factors for the development of urinary tract infection by *Enterococcus* include indwelling urinary catheters, instrumentation of the urinary tract, structural abnormalities of the urinary tract, and previous broad-spectrum antimicrobial therapy.^{200,206} The increasing problem of nosocomial enterococcal urinary tract infection⁸⁶ is compounded by the growing problem of multiantibiotic-resistant enterococci.³⁷ While the emergence of multidrug resistance is certainly concerning, a multicenter survey of antimicrobial susceptibility among pediatric uropathogens in the United States revealed that 99% of *E. faecalis* were susceptible to amoxicillin,²⁸⁸ although this study was biased toward community-acquired isolates.

The genitourinary tract reportedly is the most common entry site leading to enterococcal bacteremia in adults,^{104,155} but it is implicated much less frequently in the cause of enterococcal bacteremia in children.^{22,25,63} Christie and colleagues⁵¹ reported that urosepsis was the cause of 12% of episodes of nosocomial enterococcal bacteremia in one children's hospital, but Das and Gray⁶³ failed to detect any cases of urosepsis in 75 consecutive cases of enterococcal bacteremia in another pediatric hospital during a 3-year period. Other complications of enterococcal urinary tract infection in adults include prostatitis and perinephric abscess.¹⁹⁵

Endocarditis

Enterococcal endocarditis was reported first in 1906,⁴ and these organisms are important causes of native-valve and prosthetic-valve endocarditis in children and adults.^{2,4,186,240} Either normal or previously damaged valves may be involved. Enterococci cause approximately 5% to 20% of cases of native-valve endocarditis in adults (excluding cases in intravenous drug users),¹⁸⁶ approximately 6% to 7% of prosthetic-valve endocarditis,^{186,293} and approximately 5% to 10% of endocarditis in intravenous drug users.²⁰⁶ Enterococcal endocarditis in intravenous drug users generally involves the aortic or mitral valves, unlike staphylococcal endocarditis in this setting, which usually involves the tricuspid valve.²⁰⁶ As with other enterococcal infections, *E. faecalis* causes most cases of endocarditis.

Enterococcal endocarditis primarily is a disease of older men, and the genitourinary tract is the most commonly identified source of the initial bacteremia. Enterococci are relatively less frequent causes of endocarditis in children—less than 5% of cases in most series.^{135,136,278,279,289,317} Typically enterococcal endocarditis occurs after a subacute course that is clinically indistinguishable from that caused by streptococci.¹⁸⁶ Although the enterococcus is a common neonatal pathogen,⁷¹ reports of neonatal enterococcal endocarditis are extremely rare.²⁸⁹ The prognosis of enterococcal prosthetic-valve endocarditis is somewhat better than that of native-valve endocarditis caused by these organisms.^{2,240} Aortic-valve involvement is associated with increased rates of morbidity and mortality.¹⁸⁶ Endocarditis rarely complicates nosocomial enterococcal bacteremia.^{175,206,227} Consequently VRE-associated endocarditis is a rare development, although cases have been reported even in neonates.^{14,281}

Bacteremia

Enterococcal bacteremia often represents a conundrum. Bacteremia in severely ill hospitalized patients, particularly that caused by VRE organisms, is associated with considerable morbidity and mortality. However, only a portion of that morbidity and mortality can be attributed directly to enterococcal bacteremia per se. Nosocomial enterococcal bacteremia frequently occurs as a component of polymicrobial bacteremia, with

*References 25, 37, 51, 75, 90, 91, 114, 153, 183, 194, 217, 244, 315.

21% to 45% of bloodstream isolates of *Enterococcus* being accompanied by one or more other pathogens.^{63,175,227,271} As many as half of cases of catheter-related enterococcal bacteremia are polymicrobial.^{183,227} Pammi et al. found that *Enterococcus* spp. were more common as a contributor to polymicrobial bacteremia (14.9%) than monomicrobial bacteremia (6.9%) in neonates.²²⁴ Many,^{112,175} but not all,^{122,183} series of patients with enterococcal bacteremia have reported increased mortality rates in patients with polymicrobial bacteremia (including *Enterococcus*) versus isolated enterococcal bacteremia. Mortality in adults with nosocomial enterococcal bacteremia has ranged from 23% to 46%,^{175,176,227} but patients at risk for the acquisition of nosocomial enterococcal bacteremia are severely ill and have a poor prognosis independent of the bacteremic event. However, hospital-acquired enterococcal infections can be life-threatening,^{76,206,227,232} and specific therapy does appear to reduce the overall mortality rate.^{77,123,227} Furthermore a meta-analysis concluded that vancomycin resistance is independently correlated with increased mortality in patients with enterococcal bloodstream infections.^{69,70} Nonetheless many episodes of enterococcal bacteremia in high-risk patients apparently resolve in the absence of specific therapy.^{123,297} The mortality rate associated with enterococcal bacteremia in children has been lower than that reported in adults in most studies but has ranged from 7.5%⁶³ to 12% with some series as high as 20%²² to 26%,⁵¹ depending on the population studied.

In adults, many cases of enterococcal bacteremia are associated with a primary focus, most commonly a urinary tract infection.^{67,106} In contrast, few children with enterococcal bacteremia have urosepsis, and most episodes of enterococcal bacteremia in children have not been associated with any identifiable focus.^{25,242} However, Christie and coworkers⁵¹ identified a primary focus in 21 of 57 children (37%) with nosocomial enterococcal bacteremia, including seven patients with urosepsis and six with peritonitis. Many children with enterococcal bacteremia do have underlying disease involving the gastrointestinal or respiratory tract.^{22,25} Central venous catheter-related enterococcal bacteremia is a significant problem in both children^{22,25,51,63,71,227} and adults.^{103,227} In earlier series, infections of vascular catheters were reported to account for only 2% to 14% of cases of enterococcal bacteremia,¹⁰⁴ but subsequent reports have implicated intravascular devices in as many as 22% to 28% of these episodes in adults and children.^{63,227} Nosocomial transmission appears to be a factor in the development of VRE bacteremia in children and, in at least one study, played a larger role than individual patient exposure to vancomycin.⁶⁵

Most episodes of enterococcal bacteremia do not lead to endocarditis,^{175,206,227} and endocarditis is particularly uncommon in the setting of nosocomial enterococcal bacteremia. Maki and Agger¹⁷⁵ identified only one case of endocarditis in 118 episodes of hospital-acquired enterococcal bacteremia, whereas endocarditis was diagnosed in 12 of 35 patients with community-acquired enterococcal bacteremia.

Intraabdominal Infections

Most of the published information about the role of *Enterococcus* in intraabdominal and pelvic infections comes from series of adult patients. Enterococci commonly are isolated as components of polymicrobial infections involving the abdomen or pelvis,¹⁰² and animal models suggest that these organisms can play a synergistic role in the pathogenesis of such infections.¹³³ However, evidence that the addition of specific antienterococcal therapy improves the outcome of human intraabdominal and pelvic infections, even when enterococci are isolated from peritoneal cultures, is not compelling.¹⁰²

Children with enterococcal bacteremia frequently have underlying conditions related to the gastrointestinal tract.^{22,25,51} Bonadio²² reported five cases of enterococcal bacteremia in previously healthy infants with gastroenteritis, six cases associated with bowel obstruction, and one case associated with acute appendicitis without perforation. Boulanger and coworkers²⁵ identified underlying conditions affecting the gastrointestinal system in eight of 32 pediatric patients, but they were unable to specifically implicate any of these conditions as the source of the bacteremia. Das and Gray⁶³ detected underlying chronic gastrointestinal pathology (short-gut syndrome, congenital anomalies of the gastrointestinal tract, ulcerative colitis, chronic liver disease) in fully a third (25 of 75) of pediatric patients with enterococcal bacteremia.

Meningitis

Enterococci are rare causes of bacterial meningitis in adults and children. Stevenson and colleagues²⁸² found only four cases of enterococcal meningitis among 493 episodes (0.8%) of bacterial meningitis in adults, and they identified an additional 90 cases in a literature search of the interval from 1966 to 1992. These authors reviewed 16 published cases of enterococcal meningitis in children: 11 of these 16 pediatric cases were complications of central nervous system (CNS) trauma or surgery, but four children (three of the four were neonates) had primary meningitis.²⁸² Enterococci are uncommon but well-recognized causes of infection involving cerebrospinal fluid (CSF) shunts and related devices.^{131,152,209,261,316} Meningitis rarely complicates nosocomial bacteremia in adults,^{175,227} but it has been reported more frequently in children (particularly neonates) with bacteremia. For example, meningitis developed in 7% (four of 57) of episodes of nosocomial enterococcal bacteremia in children in Cincinnati⁵¹ and in 15% (four of 26) of premature neonates with late-onset enterococcal sepsis in Houston.⁷¹

Stevenson and associates²⁸² found that most adults with enterococcal meningitis were immunocompromised (most were receiving steroids) or had a history of CNS, surgery, or both. Enterococcal meningitis has been reported in an adult patient with HIV infection who had completed a course of steroids for presumed *Pneumocystis pneumonia*.²²⁹ Although many children with enterococcal meningitis do have a history of CNS trauma or surgery or are premature infants, most do not have other identifiable predisposing conditions or a history of immunosuppressive therapy. As with the majority of enterococcal infections, most isolates from CSF are *E. faecalis*, but meningitis and ventriculoperitoneal shunt infections caused by *E. faecium* also have been reported in children and adults.^{209,211,230}

Neonatal Infections

Enterococci are important neonatal pathogens,* and the published experience with neonatal enterococcal infections constitutes much of the pediatric experience with these organisms. Although several large series of neonatal sepsis included few cases of enterococcal infection,¹⁵¹ many centers have reported that *Enterococcus* is a relatively frequent cause of neonatal bacteremia. Siegel and McCracken²⁷³ found that enterococci were second only to group B streptococci as causes of neonatal sepsis at Parkland Hospital in Dallas from 1974 to 1977, with an incidence rate of approximately one case per 1000 live births. Gladstone and colleagues⁹⁸ reported that *Enterococcus* caused 18 of 270 (6.7%) episodes of neonatal sepsis at Yale–New Haven Hospital during the period 1979 to 1988, which ranked fourth in incidence behind group B streptococci (64 cases; 23.7%), *E. coli* (46 cases; 17.0%), and coagulase-negative staphylococci (36 cases; 13.3%). During the 1990s, reports from Houston,⁷¹ Cincinnati,⁵¹ and New York City¹⁸³ documented sharp increases in the rate of late-onset neonatal infection with enterococci in both hospitalized high-risk premature neonates and infants^{71,183} and otherwise healthy term newborns with “community-acquired” infection.⁷¹ By contrast, a study of otherwise healthy term infants aged 1 week to 3 months cared for in the Kaiser Permanente Health System revealed that *E. faecalis* accounted for one of 92 culture confirmed cases of bacteremia from 2005 to 2009.¹¹¹

Enterococci cause both early-onset (<7 days of age) and late-onset (>7 days of age) neonatal sepsis. Early-onset disease is indistinguishable from that caused by other neonatal pathogens, but it tends to be less severe.⁷¹ Dobson and Baker⁷¹ identified 56 neonates with enterococcal sepsis during a 10-year period at Jefferson Davis Hospital in Houston; 18 of 56 (32%) had early-onset sepsis, 26 of 56 (46%) had late-onset sepsis, and 12 of 56 (21%) had sepsis associated with necrotizing enterocolitis (2 early onset, 10 late onset). In this study, 25 of 26 (96%) infants with late-onset enterococcal sepsis were premature infants. Christie and colleagues⁵¹ identified 83 cases of enterococcal bacteremia between 1986 and 1992 at Children’s Hospital of Cincinnati; 58 of the 83 episodes occurred in neonates. Most cases (57 of 83; 68.7%) were

*References 7, 9, 39, 40, 44, 59, 77, 85, 98, 110, 115, 116, 146, 162, 173, 195, 199, 203, 206, 207, 214, 234, 243, 243, 246.

nosocomial, but many (26 of 83; 31.3%) were community acquired. Young infants (<3 months of age) accounted for almost all (24 of 26; 92.3%) of the community-acquired episodes and for many (34 of 57; 59.6%) of the nosocomial infections. Bonadio²² and Boulanger and colleagues²⁵ also reported community-acquired enterococcal bacteremia in young infants.

McNeeley and associates¹⁸³ identified 138 episodes of enterococcal bacteremia in a New York City neonatal ICU during a 20-year period and reviewed 100 of the episodes in detail. These authors noted a sharp increase in the rate of enterococcal bacteremia during the second decade (1984–94) of this study and found that most cases occurred in older infants; during this decade, the mean age at onset was 44.7 days (vs. 16.1 days during the first decade of the study), and 65% (51 of 78) of the episodes occurred after the infants reached 30 days of age. Most of the infections occurred in neonates with indwelling central venous catheters (77%), and more than half of the patients had evidence of gastrointestinal disease (necrotizing enterocolitis in 33% and abdominal distention in an additional 21%). The overall mortality rate in this study was 28%, although many of the deaths were not attributed to the enterococcal infection. Most (64%) of the episodes of enterococcal bacteremia in this series were polymicrobial.¹⁸³ In a recent 10-year survey by Bizarro et al., *E. faecalis* accounted for 13% of 368 episodes of late-onset neonatal sepsis.²¹ Enterococci are an uncommon but known cause of neonatal meningitis; in a recent study from the United Kingdom of 256 episodes of meningitis among infants younger than 90 days, a single case was attributed to *E. faecalis*.¹²⁸ By contrast, in a study from Dallas, Texas, two of 21 meningitis cases in febrile infants younger than 60 days were caused by *E. faecalis*.³³

Nosocomial outbreaks of enterococcal infection, including VRE infection, have been reported in several neonatal units in the United States.^{51,59,173,234,238} Indwelling central venous catheters, necrotizing enterocolitis, and intraabdominal surgery are important predisposing factors for the development of nosocomial enterococcal bacteremia in neonates, whereas the genitourinary tract is implicated much less frequently as a source.^{51,183} Colonization with VRE in the NICU at Parkland Hospital in Dallas, Texas, was associated with a strain that was considered endemic among adult nonobstetric inpatients at their institution, underscoring the potential for transfer of drug-resistant pathogens from one hospital unit to another.²³⁴

Enterococcal bacteremia in neonates and young infants has been associated with diarrhea and respiratory disease,^{22,71} although a causative role for *Enterococcus* in the pathogenesis of gastroenteritis or pneumonia remains undefined. Enterococci rarely cause urinary tract infections in neonates,^{22,51,71,183} but nosocomial and community-acquired cases have been reported. Enterococci have been noted to cause a variety of other neonatal infections, including focal skin and soft tissue infections such as scalp abscess,⁷¹ omphalitis,⁷¹ and conjunctivitis.³⁰¹

Most enterococcal infections in neonates are caused by *E. faecalis*, but outbreaks of infection with *E. faecium* have been reported.⁵⁹ In the series from Cincinnati consisting largely of neonates, 82% of enterococcal isolates were *E. faecalis* and 14% were *E. faecium*.²⁰ McNeeley and colleagues¹⁸³ reported the isolation of *E. faecalis* from 94/100 patients and *E. faecium* from 15 of 100 patients in their series (both organisms were isolated from nine of the patients). Six of the *E. faecium* isolates were resistant to vancomycin, and all six patients with VRE bacteremia died, although only one death appeared to be related directly to the VRE infection.

Septic Arthritis

Enterococci rarely have been reported to cause septic arthritis, but they can infect native or prosthetic joints. Raymond and colleagues²³⁵ reported a case of enterococcal septic arthritis involving a prosthetic hip and reviewed an additional 18 cases from the literature. Of these 19 episodes, 11 involved prosthetic joints (two hips, nine knees), and eight involved native joints; only one of the eight individuals with native-joint arthritis had an underlying abnormality of the joint. In seven of the 19 episodes, *Enterococcus* was isolated from synovial fluid, along with a second organism (three with coagulase-negative staphylococci, one with group B streptococci, one with *Pseudomonas*, one with *Streptococcus*, and one with *Kingella kingae*). Only one pediatric case was identified: a 21-month-old girl with septic arthritis of the wrist whose joint aspirate grew

Enterococcus spp. and *K. kingae*.²⁷² Other musculoskeletal infections such as osteomyelitis and pyomyositis secondary to enterococci have been reported; however, these are also quite rare.^{248,302}

DIAGNOSIS

Enterococcal infections usually are diagnosed by isolation of *Enterococcus* from a culture of blood or another normally sterile site. As discussed earlier, enterococci are ubiquitous inhabitants of the human gastrointestinal tract, and isolation of these organisms from stool or surface cultures is not evidence of invasive infection. Although enterococci are uncommon blood culture contaminants, transient bacteremia, pseudobacteremia, or both may be caused by these organisms.^{123,297}

More problematic is the interpretation of a positive culture for enterococcus as a component of polymicrobial infections, particularly intraabdominal and pelvic infections. In this setting, the role of the enterococcus in pathogenesis is unclear, and therapeutic regimens that do not include antienterococcal agents usually suffice to effect a clinical cure.¹⁰² However, rare cases of breakthrough enterococcal bacteremia have been reported with these regimens, and one study found a decreased rate of abdominal surgical wound infections when antienterococcal coverage was provided in a prophylactic regimen.³⁰⁶

ANTIMICROBIAL SUSCEPTIBILITY AND RESISTANCE

The increasing importance of *Enterococcus* as a human pathogen, especially in the nosocomial setting,^{37,78,141,183,194,206,244,314,315} is of particular concern because of the concomitant development of antimicrobial resistance by these organisms. Furthermore antibiotic resistance probably has played a critical role in allowing the organism to persist and eventually cause disease in high-risk patients despite its relatively low virulence.

Some enterococci have acquired high-level resistance to all three classes of antimicrobial agents that traditionally have been used to treat life-threatening enterococcal infections— β -lactams, aminoglycosides, and glycopeptides. This acquired resistance has occurred in the context of intrinsic (usually lower level) resistance of enterococci to many antibiotics, and physicians have been confronted with the possibility that invasive disease caused by these organisms might not respond to any available antibiotics. Some enterococci also have acquired resistance to recently developed agents (e.g., linezolid, daptomycin) that are active against most antibiotic-resistant gram-positive cocci (see later discussion). The molecular basis of enterococcal resistance to commonly used antimicrobials is summarized in Table 84A.1.

Intrinsic Resistance

β -Lactam Antibiotics

Relative resistance to β -lactam antibiotics is an intrinsic characteristic of enterococci that occurs even in human populations without previous exposure to antibiotics¹⁹⁰; such resistance is due to the lower affinity of enterococcal (vs. streptococcal) penicillin-binding proteins, especially PBP-5.^{195,309} In general, the minimal inhibitory concentration (MIC) of penicillin for most *E. faecalis* isolates (2 to 8 $\mu\text{g/mL}$) is at least 10 to 100 times higher than that of most streptococci, and *E. faecium* is even more resistant (MIC of 8 to 32 $\mu\text{g/mL}$ or higher).²⁰⁶ Ampicillin is the most active of the β -lactam antibiotics against enterococci, with average MIC values approximately twofold lower than those for penicillin.^{190,195,206} Nafcillin generally is less active than penicillin, and methicillin is much less active (MIC >50 $\mu\text{g/mL}$ for *E. faecalis*), as is ticarcillin. Importantly enterococci exposed to β -lactam antibiotics rapidly become tolerant of the killing effects of these agents.^{195,206} Along with intrinsic resistance to these agents, tolerance limits the utility of β -lactam monotherapy for the treatment of endocarditis or other severe enterococcal infections.

Imipenem has some activity against *E. faecalis* but is much less active against *E. faecium*.^{195,206} None of the cephalosporins currently approved for use in pediatrics has clinically useful activity against the enterococci, and frequent use of broad-spectrum cephalosporins and imipenem has been identified as a risk factor for the acquisition of nosocomial enterococcal infection.

TABLE 84A.1 Summary of *Enterococcus* spp. Mechanisms of Resistance to Commonly Used Antimicrobials

Antimicrobial	Intrinsic or Acquired Resistance	Acquired Genes/ Gene Products, Method of Acquisition	Mechanism	Comments
β-lactams	Intrinsic		Decreased affinity of PBP5 for β-lactams. Alterations in PBP5 may confer high-level ampicillin resistance in <i>E. faecium</i> . Rarely can possess a plasmid-mediated β-lactamase.	Ampicillin has lower MICs for <i>Enterococcus</i> spp. than any other β-lactam.
Aminoglycosides	Intrinsic		All enterococci exhibit relative resistance to aminoglycosides (lack of bactericidal activity) because of diminished intracellular uptake of these drugs. <i>E. faecium</i> produce an acetyltransferase that confers complete resistance to some aminoglycosides (tobramycin, kanamycin, etc.).	Increased bacterial uptake of aminoglycosides in the presence of a cell wall active antibiotic has been described.
High-level aminoglycoside resistance (HLAR)	Acquired	AAC(6′)-Ie/APH (2′)-Ia APH (2′)-Ic aadA/ANT(3′) (specific to streptomycin)	High-level gentamicin resistance through acquisition of a dual function enzyme with a combination of acetyltransferase and phosphotransferase. Streptomycin resistance acquired through acquisition of an adenyltransferase.	HLAR eliminates synergism with cell wall active antibiotics (β-lactams and glycopeptides).
Glycopeptides	Acquired	<i>vanA</i> , <i>vanB</i>	Alteration of peptidoglycan pentapeptide crosslink from d-Ala-d-Ala to d-Ala-d-Lac or d-Ala-d-Ser.	<i>VanA</i> phenotype associated with resistance to vancomycin and teicoplanin, more commonly seen in <i>E. faecium</i> . <i>VanB</i> phenotype associated with resistance to vancomycin but not teicoplanin, more commonly seen in <i>E. faecalis</i> . Other <i>van</i> phenotypes are very uncommon in human clinical isolates.
Oxazolidinones (linezolid)	Acquired	Multiple copy mutations in genes for 23s rRNA L3 or L4 ribosomal protein mutations <i>cfr</i> methyltransferase	Altered drug target	
Daptomycin	Acquired	Mutations within LiaFSR system which helps regulate cell membrane homeostasis	Unclear mechanism but likely involves alterations in phospholipid metabolism.	Lipopeptide resistance remains rare with >99% isolates susceptible
Streptogramins (Quinupristin-Dalfopristin)	Intrinsic (<i>E. faecalis</i>) Acquired (<i>E. faecium</i>)	<i>E. faecalis</i> (intrinsic): <i>Isa</i> encoding a presumptive efflux pump <i>E. faecium</i> (acquired): <i>VatD</i> and <i>VatE</i> acetyltransferases, <i>VgbA</i> , <i>VgbB</i>	Possible efflux of drug in <i>E. faecalis</i> . Modification of drug in <i>E. faecium</i> .	All <i>E. faecalis</i> are intrinsically resistant but is a rare finding among <i>E. faecium</i> .

Aminoglycosides

Enterococci are intrinsically resistant to all aminoglycosides because of diminished uptake of these drugs. For most *E. faecalis* isolates, the MIC for gentamicin or tobramycin ranges from 8 to 64 µg/mL and for streptomycin ranges from 12 to 250 µg/mL.^{185,228,294} Moellering and Weinberg¹⁹² and Zimmerman and colleagues³²⁰ first demonstrated that the addition of a cell wall-active antibiotic results in dramatically increased aminoglycoside uptake by enterococci and that combinations of β-lactam and aminoglycoside antibiotics can lead to synergistic killing of these organisms. All *E. faecium* strains exhibit higher MICs than does *E. faecalis* to certain aminoglycosides, including tobramycin, netilmicin, kanamycin, and sisomicin, and these aminoglycosides do not exhibit synergy with β-lactam antibiotics against *E. faecium*.^{49,206}

Other Antibiotics

Under carefully standardized laboratory conditions, enterococci are inhibited by the combination of trimethoprim and sulfamethoxazole

(TMP-SMX). However, *Enterococcus* isolates should be considered resistant to TMP-SMX because these organisms are capable of using exogenous folinic acid to evade the antimicrobial action of TMP-SMX.³¹⁹ TMP-SMX fails to eradicate enterococci in animal models of infection,^{43,109} and breakthrough enterococcal bacteremia has occurred in patients being treated with TMP-SMX for enterococcal urinary tract infection.¹⁰¹ Enterococci also are intrinsically resistant to clindamycin, a drug with excellent activity against many other gram-positive cocci. Most enterococci have a clindamycin MIC of 12.5 to 100 µg/mL.²⁰⁶ As with low-level β-lactam resistance, clindamycin resistance is found in enterococcal isolates from human populations with no previous antibiotic exposure.¹⁹⁰

Acquired Resistance

Enterococci have acquired resistance to antibiotics by the acquisition of both narrow and broad host range plasmids and via the exchange of conjugative transposons.²⁰⁶ Resistance mediated by broad host range

plasmids is of particular concern because glycopeptide resistance encoded by broad host range plasmids has been transferred to staphylococci in vitro²¹⁶ and in vivo.^{36,38,292,305}

High-Level Resistance to Aminoglycosides

Intrinsic resistance of enterococci to aminoglycosides is caused by poor drug uptake by these organisms and can be overcome effectively both in vitro and in vivo by the addition of cell wall-active antibiotics. In contrast, high-level resistance to aminoglycosides is mediated either by the acquisition of plasmids encoding aminoglycoside-modifying enzymes (affecting all aminoglycosides via several different enzymes) or by ribosomal mutations (streptomycin only). High-level aminoglycoside resistance is of great clinical importance because it eliminates synergism between the affected aminoglycoside or aminoglycosides and β -lactam or glycopeptide antibiotics.^{49,206,228} All *E. faecium* strains produce a chromosomally encoded aminoglycoside acetyltransferase that eliminates synergistic killing between cell wall-active antibiotics and certain aminoglycosides (including tobramycin, kanamycin, netilmicin, and sisomicin),⁴⁹ but it does not result in high-level resistance to these compounds. Consequently these particular aminoglycosides should not be used to treat infections caused by *E. faecium*.

Enterococci with high-level resistance (MIC usually ≥ 2000 $\mu\text{g/mL}$) to streptomycin, kanamycin, and several other aminoglycosides (excluding gentamicin) were identified more than 40 years ago¹⁹³ and were widely prevalent in the United States by the mid-1970s.³² High-level resistance to streptomycin occurs via two mechanisms, ribosomal mutation or enzymatic modification by 6'-adenylyltransferase. Initial reports of high-level resistance to kanamycin were associated with the production of 3'-phosphotransferase.^{49,206}

Horodniceanu and colleagues¹²⁵ first reported high-level resistance to gentamicin in *E. faecalis* in 1979, and this resistance was shown later to be mediated by a fusion enzyme containing both 6'-acetyltransferase and 2''-phosphotransferase activity. Expression of this fusion enzyme conferred resistance to all clinically useful aminoglycosides except streptomycin.^{161,162} Enterococci expressing this fusion protein usually have gentamicin MICs that are 2000 $\mu\text{g/mL}$ or higher. Thus, enterococci expressing this fusion enzyme and the 6'-adenylyltransferase mediating streptomycin resistance (or chromosomally mediated streptomycin resistance) are highly resistant to all available aminoglycosides and generally fail to be killed synergistically by any combination of β -lactam antibiotics and aminoglycosides. Strains of *E. faecalis* resistant to both streptomycin and gentamicin (and thus to all aminoglycosides) were detected first in Houston, Bangkok, and Santiago in 1983.^{185,206} Subsequently strains of *E. faecalis*, *E. faecium*, and other enterococci resistant to gentamicin, streptomycin, or both (or all) aminoglycosides have become increasingly prevalent^{103,137,138,140,170,228} (see Table 84A.2). Although high-level resistance to both streptomycin and gentamicin was described first in *E. faecalis*, it now is at least as common in *E. faecium*.¹³⁹

Enterococci resistant to all aminoglycosides frequently have been isolated from clinical specimens for the past 2 decades. Jones and colleagues and the *Enterococcus* Study Group¹³⁸ found that fully 20% of 1936 enterococcal isolates from late 1992 (from 97 participating laboratories in 47 states) exhibited high-level resistance to both gentamicin and streptomycin. Low and associates and the SENTRY Antimicrobial Resistance Surveillance Program¹⁷⁰ reported similar rates of high-level resistance to both gentamicin and streptomycin from 1997 to 1999 (see Table 84A.2). Almost a third (32.8%) of enterococci collected by the SENTRY group from 1997 to 2005 were highly resistant to gentamicin.¹⁴⁰ Many medical centers in the United States now report that most enterococcal isolates exhibit high-level resistance to all aminoglycosides.²⁰⁷

Several new aminoglycoside-resistant genes were identified in enterococci during the late 1990s.⁴⁹ Some enterococci produce three or more enzymes. Strains expressing some of the recently described resistant genes may fail to exhibit synergy between gentamicin and β -lactams despite MICs below those usually associated with high-level resistance. For example, the *aph* (2'')-Ic gene⁴⁸ found in clinical isolates of both *E. faecalis* and *E. faecium* results in gentamicin MICs of approximately 256 to 384 $\mu\text{g/mL}$, lower than the standard screening cutoff for high-level resistance to gentamicin (500 $\mu\text{g/mL}$). Nonetheless these organisms are

resistant to ampicillin-gentamicin synergism and would not be detected by standard screening methods.

High-Level Resistance to β -Lactams and Production of β -Lactamase

The mechanisms of resistance to penicillin, ampicillin, and other β -lactam antibiotics differ among enterococcal species. High-level β -lactam resistance (ampicillin MIC ≥ 16 $\mu\text{g/mL}$) of *E. faecium*^{27,108,180} and some other non-*faecalis* enterococcal strains²⁷ is now common and is mediated by additional alterations in penicillin-binding proteins (PBPs), particularly PBP-5.^{89,108,241} Thus high-level resistance to ampicillin and other β -lactams in *E. faecium* (and other non-*faecalis* strains) represents an exaggerated form of intrinsic β -lactam resistance. *E. faecalis* isolates also are intrinsically resistant to β -lactams (though less so than *E. faecium*), but little change has occurred in the level of this resistance in recent years. However, some strains of *E. faecalis*^{139,203,202} and *E. faecium*⁵⁸ have acquired clinically significant resistance to ampicillin and penicillin via the plasmid-mediated, constitutive production of a β -lactamase enzyme identical to that of *S. aureus*.³²¹ β -Lactamase-producing strains of *E. faecalis* and *E. faecium* will not be detected by routine susceptibility testing because of a pronounced inoculum effect. Therefore enzymatic methods such as the nitrocefin test must be used to screen for β -lactamase-producing strains.^{147,203} Fortunately such strains remain very uncommon.^{5,195}

Glycopeptide Resistance

Enterococci resistant to vancomycin were identified first in 1988^{158,298} and rapidly have become a major nosocomial problem. Data collected by the CDC NNIS revealed a dramatic increase in the rate of vancomycin resistance in nosocomial isolates of *Enterococcus* during the interval 1989 to 1993.³⁷ The NNIS survey documented a 26-fold increase in vancomycin resistance among all nosocomial isolates (from 0.3% of enterococcal isolates in 1989 to 7.9% in 1993) and a 34-fold increase in vancomycin resistance among isolates obtained from adult patients in ICUs (from 0.4% of isolates in 1989 to 13.6% in 1993). Rates of vancomycin resistance in enterococci continued to increase during the next decade (Table 84A.2). The NNIS reported that fully 25% of enterococci associated with nosocomial infections in adult patients in ICUs in the United States were resistant to vancomycin in 1999 and 2000; by 2003 to 2004, approximately 30% of the enterococcal isolates from these patients were vancomycin resistant. (See CDC website: http://www.cdc.gov/ncidod/dhqp/pdf/ar/ICU_RESTrend1995-2004.pdf.) Isolates of *E. faecium* are particularly likely to be vancomycin resistant. Jones and colleagues¹⁴⁰ in the SENTRY Antimicrobial Resistance Surveillance Program reported that 69.4% of 1512 US bloodstream isolates of *E. faecium* collected between 1997 and 2005 were resistant to vancomycin. Similarly Wisplinghoff and colleagues³¹⁴ in the SCOPE surveillance study found that 60% of US bloodstream isolates of *E. faecium* collected between 1995 and 2002 were resistant to vancomycin, whereas only 3% of *E. faecalis* bloodstream isolates were vancomycin resistant.

Enterococci were the second most common organisms associated with pediatric bloodstream infections in both the 1992 to 1997 NNIS database²⁴⁶ and the pediatric component of the 1995 to 2001 SCOPE survey.³¹⁴ However, VRE organisms were detected much less frequently in these pediatric patients: only 11% of *E. faecium* and 1% of *E. faecalis* bloodstream isolates (of 357 total enterococcal isolates) obtained from pediatric patients in the SCOPE study were vancomycin resistant.³¹⁴ This finding is important because vancomycin-resistant isolates, particularly those of *E. faecium*, also may exhibit high-level resistance to both β -lactam antibiotics and aminoglycosides, thus rendering treatment of these infections extremely challenging.*

Vancomycin resistance among enterococci is phenotypically and genotypically heterogeneous^{7,99,204,207} and may or may not be associated with resistance to other glycopeptides, including teicoplanin. Five major phenotypes of vancomycin resistance (VanA, VanB, VanC, VanD, and VanE) have been well characterized in *Enterococcus* spp. The VanA and VanB phenotypes are most common, and both are transferable. The VanA phenotype is characterized by high-level resistance to vancomycin and teicoplanin, whereas strains with the VanB phenotype exhibit variable

^aHowever, 11/632 (1.7%) *E. faecalis* isolates were β-lactamase producers.

^bNo β-lactamase-producing strains were identified.

^cOnly two β-lactamase-producing isolates were identified.

levels of resistance to vancomycin but not teicoplanin.^{7,99,206,207} The VanC phenotype is limited to *E. gallinarum* and *E. casseliflavus* and is associated with constitutive, low-level, chromosomally mediated (nontransferable) resistance to vancomycin but not teicoplanin.^{99,206,207,242} VanD and VanE phenotypes occur uncommonly and are not transferable.

High-level resistance to both vancomycin and teicoplanin (the VanA phenotype) is found primarily in strains of *E. faecium*, whereas most vancomycin-resistant strains of *E. faecalis* express the VanB phenotype and remain susceptible to teicoplanin. Jones and associates and the *Enterococcus* Study Group found that 10 of 11 (91%) vancomycin-resistant strains of *E. faecalis* remained susceptible to teicoplanin (VanB phenotype), whereas 49 of 62 (79%) vancomycin-resistant strains of *E. faecium* were resistant to teicoplanin (VanA phenotype).¹³⁹

The biochemical mechanisms responsible for the major vancomycin-resistant phenotypes are the subject of intense study.^{99,205} Glycopeptides prevent cross-linkage of peptidoglycan through binding to the terminal d-Alanine (Ala)-D-Ala residues on the N-acetylmuramic acid component of the cell wall. This in turn interferes with the formation of a glycine pentapeptide that links individual peptidoglycan chains. Vancomycin resistance in enterococci is mediated through alteration of d-Ala-d-Ala to D-Ala-D-lactate (Lac) or D-Ala-D-Serine (Ser). Both VanA and VanB phenotypes are mediated by homologous enzymes that catalyze the formation of an altered, vancomycin-resistant D-Ala-D-Lac peptide that is incorporated into cell wall peptidoglycan for which vancomycin has diminished affinity.^{7,207,242} The *vanA* and *vanB* gene clusters share functional similarities but are regulated quite differently.^{99,207} VanA resistance is transferable by either a transposon or conjugative plasmids. VanB resistance often is encoded by chromosomal DNA but may be transferred by at least two different transposons.^{99,207} Vancomycin induces the production of enzymes encoded by both the *vanA* and *vanB* gene clusters, whereas teicoplanin induces VanA but not VanB enzymes.⁹⁹

Resistance to Other Antibiotics

Recently licensed antimicrobials active against most antibiotic-resistant, gram-positive cocci (including VRE organisms) include linezolid and daptomycin. The minocycline derivative tigecycline also is active against most enterococci but has not been well studied for the treatment of these infections. Finally, another agent, the streptogramin quinupristin-dalfopristin, is active against *E. faecium* but not *E. faecalis* isolates and, because of this limitation and its considerable toxicity, it has little utility in pediatrics.

The oxazolidinones are a novel class of synthetic protein synthesis inhibitors that act to inhibit the formation of ribosomal initiation complexes in bacteria.⁵³ Linezolid, the first oxazolidinone antimicrobial approved for human use, is active against both *E. faecalis* and *E. faecium*, including most VRE isolates. Initial studies demonstrated virtually uniform activity of this agent against clinical isolates of enterococci,^{24,81,219} with 100% of 180 strains (representing multiple resistance profiles) inhibited by linezolid concentrations of 1 to 4 µg/mL in one study.⁸¹ Furthermore initial in vitro studies suggested that the development of resistance would occur very rarely.^{53,141,322} However, resistance to linezolid has been reported in several patients receiving prolonged courses of therapy with this drug^{4,100,178,187,264} and in some patients who have not previously received the agent,²³ and it has been associated with clinical failures.^{5,100} Resistance to linezolid is conferred by single nucleotide changes in varying numbers of copies of the bacterial genes encoding 23S ribosomal RNA.¹⁸⁷ Resistance increases in strains containing multiple copies of these mutations.^{177,187} In addition, mutations within the L3 and L4 ribosomal proteins can confer resistance to oxazolidinones in enterococci and staphylococci.⁴¹ A gene encoding a methylase known as *cfr* confers resistance to phenicols, oxazolidinones, pleuromutilins, macrolides, and streptogramins. *cfr* was first observed in staphylococci but was ultimately recognized to occur, albeit rarely, among enterococci of human origin.⁶⁸ Another gene with 75% peptide identity to *cfr* has recently been recognized in linezolid-resistant *E. faecium* isolates from New Orleans and has been termed *cfr*(B).⁶⁶ Recent work has identified a novel gene in both *E. faecalis* and *E. faecium* of animal origin, *optrA*, encoding a membrane transporter that confers resistance to both oxazolidinones and phenicols; the presence of these

gene in enterococci of human origin remains quite rare, however.³⁰⁴ Although some centers have reported increasing rates of linezolid resistance in VRE isolates¹⁸⁷ and nosocomial spread of linezolid-resistant VRE strains,¹²¹ overall rates of linezolid resistance in enterococci remain low. For example, only 0.9% of 1512 US bloodstream isolates of *E. faecium* collected from 1997 to 2005 by the SENTRY group were resistant to linezolid,¹⁴⁰ and only 0.75% of 934 enterococcal isolates studied in 2010 as part of the LEADER surveillance program were resistant to linezolid.⁸⁷

Daptomycin is a novel cyclic lipopeptide antimicrobial that exhibits rapid, concentration-dependent bactericidal activity against gram-positive pathogens, including methicillin-resistant *Staphylococcus aureus* (MRSA) and VRE strains.^{35,280} Daptomycin has a novel method of action in which binding to bacterial membranes and triggering of rapid depolarization of membrane potential lead to inhibition of protein and nucleic acid synthesis.⁹⁴ Daptomycin was found to have potent activity against a panel of VRE isolates from the United States and Europe—all 75 VRE isolates tested (i.e., 55 *E. faecium* and 20 *E. faecalis*) were susceptible to this agent.²⁵³ Daptomycin also was reported to be active against a collection of VRE strains resistant to linezolid or quinupristin-dalfopristin.³ However, daptomycin resistance has developed during therapy with this agent,^{167,201,249} although resistance rates remain very low. Sader and colleagues²⁵¹ studied 4312 *E. faecalis* isolates (195 VRE) and 2462 *E. faecium* isolates (1867 VRE) collected between 2005 and 2010; 99.98% of the *E. faecalis* isolates and 99.68% of the *E. faecium* isolates were susceptible to daptomycin. The mechanisms responsible for daptomycin resistance are poorly understood but are believed to involve genes associated with phospholipid metabolism and bacterial cell membrane integrity, specifically *liaR*, which appears to be involved in cardiolipin distribution.^{237,295}

Streptogramins are protein synthesis inhibitor antibiotics and are natural combinations of two chemically unrelated molecules, streptogramin A and B.¹⁷² Quinupristin-dalfopristin is a streptogramin agent that is active against *E. faecium* (including most strains of VREF) but lacks activity against *E. faecalis* at clinically achievable concentrations.⁵⁷ An early study found that more than 95% of 875 initial patient isolates of VREF were susceptible to quinupristin-dalfopristin,⁸⁰ but both emergence of resistance to this agent^{191,253} and superinfection with *E. faecalis* and other organisms^{46,313} have been reported during therapy with this drug. In the United States, overall rates of enterococcal resistance to quinupristin-dalfopristin remain low, in the range of 1% to 2% in most areas.¹²²

Testing for Antimicrobial Resistance in Enterococci

All enterococci isolated from cultures of blood, CSF, or other normally sterile sites (with the possible exception of urine) should be tested for resistance to β-lactam antibiotics (i.e., ampicillin, penicillin, or both, including a test for β-lactamase production), vancomycin, and high levels of aminoglycosides (streptomycin and gentamicin)^{84,235,242} by using the methodology and interpretative guidelines published by the Clinical and Laboratory Standards Institute (CLSI).⁵⁴ For multiantibiotic-resistant isolates, testing for susceptibility to alternative agents, including linezolid and daptomycin, should be performed.

Testing of enterococci for ampicillin (or penicillin) resistance must involve determination of the MIC of these agents and a test for β-lactamase production.⁵⁴ Jones and colleagues¹³⁸ and the *Enterococcus* Study Group compared three techniques that are used commonly to determine the ampicillin MIC of enterococcal isolates—disk diffusion, broth microdilution, and E-test strips—and found excellent agreement among the three methods. Enterococcal isolates with an ampicillin or penicillin MIC of 16 µg/mL or greater are considered resistant to these agents.⁵⁴ β-Lactamase-producing enterococci cannot be detected by these methods but are identified routinely by performance of the chromogenic nitrocefin assay.²⁸⁶

High-level resistance to gentamicin and streptomycin usually may be detected by either agar dilution (high-level resistance to gentamicin, MIC >500 µg/mL; high-level resistance to streptomycin, MIC >2000 µg/mL) or broth microdilution (high-level resistance to gentamicin, MIC >500 µg/mL; high-level resistance to streptomycin,

MIC >1000 µg/mL).^{54,284,286} These isolates also may be identified by disk diffusion with the use of high-content aminoglycoside disks (120-µg gentamicin disk, 300-µg streptomycin disks, ≥10-mm zone = susceptible)²⁸⁴ or high-range E-test strips.^{138,256} However, the recent identification of novel genes encoding gentamicin resistance in both *E. faecalis* and *E. faecium* has raised concern about continued use of the 500-µg/mL cutoff for detection of high-level resistance to gentamicin.⁴⁹ These enterococcal isolates are not killed synergistically by combinations of ampicillin or penicillin and gentamicin, even though gentamicin MICs are 256 to 384 µg/mL. If these isolates become more widely prevalent, modification of the standard screening procedures for high-level aminoglycoside resistance may be required.

Commercially available automated antimicrobial susceptibility testing methods may fail to detect vancomycin resistance in enterococci, particularly the VanB phenotype of moderate resistance,²⁹¹ although newer versions of these systems appear to be much more reliable.^{96,299} Routine disk diffusion testing is more dependable but requires an extended incubation time and the use of transmitted light for examination of zone size to be highly accurate.^{285,291} Agar dilution screening using brain-heart infusion agar supplemented with 6 µg/mL vancomycin reliably identifies VRE strains,^{54,286,307} as does the standard broth microdilution method.^{139,291} E-test glycopeptide strips are a useful alternative to the more cumbersome broth dilution methodology.

THERAPY FOR ENTEROCOCCAL INFECTIONS

Before the emergence of VRE infection as a major nosocomial problem in high-risk patients, the optimal management of serious enterococcal infections (especially endocarditis) was well established. Successful treatment of enterococcal endocarditis required the administration of combination therapy consisting of a cell wall-active agent (usually ampicillin) and an aminoglycoside (gentamicin or streptomycin). Combination therapy also was recommended for other potentially life-threatening enterococcal infections (e.g., sepsis or meningitis) based on the extensive experience with endocarditis. Other enterococcal infections, including urinary tract infections, responded well to monotherapy with a variety of antimicrobials.

In contrast, the optimal therapy for many infections caused by VRE strains remains uncertain. Both linezolid and daptomycin have now been used extensively for the treatment of VRE infections in adults. However, only one of these antibiotics (linezolid) has been approved for use in children, and enterococci resistant to these new agents already have been detected.^{187,201}

Treatment of Infections Caused by Antibiotic-Susceptible Enterococci

Any discussion of the treatment of serious enterococcal infection must begin with a review of the large experience in the treatment of enterococcal endocarditis. The difficulty of treating enterococcal endocarditis has been apparent since early reports showed that penicillin alone failed to cure as many as two-thirds of patients with enterococcal endocarditis but was highly effective in the treatment of streptococcal endocarditis.²⁰⁶ The early failures of penicillin therapy stimulated studies of the in vitro and in vivo effects of β-lactam antibiotics on enterococci. These studies led to the discovery that enterococci were “tolerant” of the killing effects of cell wall-active agents and provided evidence that bactericidal therapy was required to cure bacterial endocarditis reliably.

For more than 65 years, standard therapy for enterococcal endocarditis has included an aminoglycoside plus a cell wall-active agent. Hunter¹²⁷ first reported clinical evidence of synergism between penicillin and streptomycin in the treatment of enterococcal endocarditis in 1947, and this synergism subsequently was confirmed for combinations of penicillin or ampicillin and streptomycin or gentamicin, both in vitro and in vivo.²⁰⁶ Moellering and Weinberg¹⁹² first demonstrated that synergy between β-lactams and aminoglycosides was a consequence of increased aminoglycoside uptake by enterococci exposed to cell wall-active agents. Glycopeptides and aminoglycosides also exhibit in vitro and in vivo synergy against “susceptible” (not expressing high-level resistance) strains of enterococci.^{124,195}

The preferred therapy for endocarditis caused by “susceptible” strains of enterococci in both adults^{5,20,186,195,240,310} and children^{62,279} consists of combination therapy with parenteral ampicillin (or penicillin G) plus parenteral gentamicin (or streptomycin) for a minimal duration of 4 to 6 weeks.¹¹ Patients with severe penicillin allergy should be treated with vancomycin plus gentamicin or streptomycin. Selected adult patients with a short duration of symptoms and an uncomplicated course may be treated with 4-week regimens³¹⁰; most other patients, including those with mitral valve involvement, a longer duration of symptoms (especially those with symptoms for >3 months), or prosthetic valve endocarditis, probably should receive 6-week courses of therapy.^{186,310} Interestingly, several reports indicate that the prognosis of enterococcal prosthetic valve endocarditis is better than that of native valve disease, perhaps because of the generally shorter duration of symptoms before the diagnosis is made.^{186,240} Many patients with prosthetic valve endocarditis caused by enterococci can be cured without surgery. Rice and colleagues²⁴⁰ reported a 69% cure rate with medical therapy in patients with enterococcal endocarditis involving prosthetic valves.

The general consensus, based on experience with enterococcal endocarditis, is that other life-threatening enterococcal infections, including meningitis and septicemia, should be treated with bactericidal regimens.^{194,206,282} The duration of therapy for uncommon enterococcal infections such as meningitis must be individualized, although 2- to 3-week courses of antibiotics have been reported to cure enterococcal meningitis.²⁸² The optimal treatment of enterococcal bacteremia, particularly that occurring in the nosocomial setting, remains controversial. A recent retrospective study compared the outcomes of children with *E. faecalis* bacteremia without endocarditis treated with ampicillin plus synergistic gentamicin (1 mg/kg per day) with those treated with ampicillin monotherapy.¹²⁸ While only 313 patients total were included in this study, the difference in duration of bacteremia between these two groups was only 0.4 days and there was no difference in the frequency of relapse of infection. There was, however, a higher rate of acute kidney injury in the combination therapy group (18.4% vs. 9.3%). While this study has limitations, given the modest improvements in duration of bacteremia and risk of renal toxicity, it does call into question the need for combination therapy in patients without endocarditis.

The prognosis for patients with enterococcal bacteremia varies widely and often is related more closely to the underlying disease than to the enterococcal infection. In adults, single-drug regimens generally are successful in the treatment of enterococcal bacteremia, thus indicating that bactericidal therapy is not required in all cases.^{194,206}

Considerable clinical experience supports the routine use of single-drug therapy for uncomplicated enterococcal urinary tract infection and for soft tissue infection caused by enterococci. Urinary tract infections by susceptible strains of enterococci generally respond promptly to ampicillin, penicillin, nitrofurantoin, or vancomycin.^{194,195,200,206}

Treatment of Infections Caused by Antibiotic-Resistant Enterococci (Including Vancomycin-Resistant Enterococci)

Unfortunately the emergence of enterococci with clinically significant resistance to aminoglycosides, β-lactams, and glycopeptides has greatly complicated the management of endocarditis and other serious infections caused by these organisms. This discussion focuses on the management of endocarditis caused by drug-resistant enterococci because the need to provide bactericidal therapy has been well established in this setting. The general principles probably apply to the management of other life-threatening enterococcal infections (see earlier discussion).

Endocarditis caused by enterococci with high-level resistance to either streptomycin or gentamicin may be treated by substituting the other aminoglycoside in a combination regimen, but isolation of strains with high-level resistance to both aminoglycosides means that no available aminoglycoside will provide synergistic killing in concert with cell wall-active agents.^{186,206,311} Based on animal studies, some experts recommend prolonged treatment (≥8 to 12 weeks) with high-dose intravenous ampicillin given by continuous infusion in this situation (if the isolate is susceptible).^{79,195} Surgical excision of infected valves may be required in such patients.²⁴⁰ Studies in adults have shown that patients with endocarditis due to *E. faecalis* with high-level aminoglycoside resistance

can be treated with a combination of ampicillin and ceftriaxone⁹⁷; furthermore in vitro synergism is exhibited by such a combination. National guidelines now endorse the use of “double β -lactam therapy” with ampicillin plus ceftriaxone for patients with endocarditis due to enterococci with resistance to aminoglycosides but susceptibility to ampicillin.¹¹

Endocarditis and other serious infections caused by enterococci resistant to β -lactam antibiotics also are increasing in frequency.¹⁰⁸ Endocarditis caused by enterococci (usually *E. faecium*) highly resistant to β -lactams may be treated with vancomycin plus an aminoglycoside (if the strain is susceptible to vancomycin). Endocarditis caused by β -lactamase-producing strains of *E. faecalis* (or, rarely, *E. faecium*) would be expected to respond to ampicillin-sulbactam because this combination is highly effective in animal models⁷⁹; the most recent American Heart Association (AHA) guidelines however, endorse the use of a combination of vancomycin plus an aminoglycoside in this circumstance however.¹¹ Higher-dose or continuous-infusion ampicillin may be effective in the treatment of endocarditis caused by some strains of enterococci that are “resistant” to ampicillin by current guidelines (MIC ≥ 16 $\mu\text{g/mL}$) because sustained plasma concentrations in excess of 100 $\mu\text{g/mL}$ may be achieved with these regimens.²⁰⁷ However, even high-dose ampicillin therapy probably will fail to cure endocarditis caused by enterococci with ampicillin MICs greater than 64 $\mu\text{g/mL}$.^{29,99}

Enterococci resistant to vancomycin may remain susceptible to teicoplanin (VanB phenotype). Teicoplanin with or without the addition of an aminoglycoside has been used successfully in the treatment of serious enterococcal infections caused by susceptible isolates,²⁶⁰ including some cases of endocarditis^{232,260} and meningitis.¹⁶⁹ However, teicoplanin is not available in the United States, treatment of endocarditis with this agent has been associated with both treatment failure and relapse,^{232,260} and high-level teicoplanin resistance may develop even without exposure to the drug.¹¹⁸ Endocarditis caused by VanB strains of enterococci should be treated with high-dose ampicillin plus gentamicin or streptomycin if resistance to these agents is not present.

Similarly, endocarditis caused by enterococci highly resistant to both vancomycin and teicoplanin (VanA phenotype) but susceptible to β -lactams should be treated with ampicillin plus an aminoglycoside (if high-level resistance to aminoglycosides is not present). Unfortunately the VanA phenotype is associated primarily with strains of *E. faecium*, which increasingly are resistant to β -lactams.^{89,108,138} Endocarditis caused by enterococci highly resistant to both glycopeptides and β -lactams is especially difficult to treat. Combinations of ampicillin and vancomycin are not bactericidal against these isolates but may²⁷⁰ or may not³⁹ provide additive or synergistic inhibition in vitro. If high-level resistance to aminoglycosides is not present, triple-combination therapy with a β -lactam, a glycopeptide, and an aminoglycoside may achieve bactericidal activity; such combinations are reported to be highly effective in animal models of endocarditis caused by ampicillin- and vancomycin-resistant *E. faecium*.³⁴ For endocarditis caused by enterococci exhibiting high-level resistance to both gentamicin and streptomycin along with resistance to β -lactams and glycopeptides, AHA guidelines endorse the use of daptomycin or linezolid (see later discussion).

Newer Options for Treatment of Vancomycin-Resistant Enterococcal Infections

Four newer antimicrobials with activity against most VRE strains have been licensed: linezolid, daptomycin, tigecycline, and quinupristin-dalfopristin. Of these drugs, only linezolid has been approved for use in children.

Linezolid, the first oxazolidinone antibiotic, was approved by the US Food and Drug Administration (FDA) in April 2000 for the treatment of selected infections caused by antibiotic-resistant, gram-positive bacteria in adults, including those caused by VRE strains (*E. faecium* or *E. faecalis*). In December 2002, the FDA approved this agent for treatment of pediatric patients with pneumonia, skin and skin structure infections, and VREF infections. Linezolid is available in both parenteral and oral formulations (with comparable bioavailability). Linezolid is active against many antibiotic-resistant, gram-positive pathogens, including MRSA, penicillin-resistant *S. pneumoniae*, and vancomycin-resistant isolates of both *E. faecium* and *E. faecalis*.^{24,53,80,87,219} This agent is bacteriostatic against most susceptible organisms, including the enterococci, but it does exhibit

bactericidal activity against some strains of pneumococci. Initial studies demonstrated virtually uniform activity of linezolid against clinical isolates of enterococci.^{24,79,220}

Linezolid has been reported to effect both bacteriologic and clinical cure in patients with life-threatening VRE infections, including endocarditis,^{10,19,45,280} bacteremia,^{45,184,220} and meningitis,^{266,316,318} although clinical experience with this agent in the treatment of endocarditis or meningitis remains limited. Linezolid therapy has been reported to cure several patients with VRE endocarditis,^{10,19,44,281} including 10 of 22 patients in one study¹⁹ and all of 3 patients who received at least 6 weeks of the drug in another report.²⁸¹ These results are encouraging, but enthusiasm for the use of linezolid to treat serious VRE infection must be tempered by its generally bacteriostatic activity and the potential for increasing resistance to this agent. Some experts suggest caution in using linezolid for treatment of VRE endocarditis because of reported therapeutic failures, toxicity, and potential for emergence of resistance.^{5,245} Pediatric experience with linezolid is not as extensive as that in the adult literature, but the drug was demonstrated to be well tolerated and as effective as vancomycin in the treatment of children with serious gram-positive infections in a large multicenter trial.¹⁴³

Linezolid generally has been tolerated well in both adults and children.^{52,93,255} Longer courses of linezolid therapy have been associated with more serious adverse effects, including optic neuropathy that usually is reversible and peripheral neuropathy that may be irreversible.^{132,247} Enterococcal resistance to linezolid remains very uncommon⁸⁷ but has been associated with clinical failures in both adults and children. A new oxazolidinone, tedizolid, has been approved by the FDA for treating skin and soft tissue infection in adults. In vitro studies have demonstrated that tedizolid remains active against enterococci with elevated MICs to linezolid and may be an additional therapeutic option in adolescents with linezolid nonsusceptible enterococci.^{13,42}

Daptomycin is a novel cyclic lipopeptide antimicrobial that exhibits rapid, concentration-dependent bactericidal activity against enterococci, including VRE strains.^{55,280} It was approved by the FDA in September 2003 for the treatment of adult patients with complicated skin and soft tissue infections caused by gram-positive bacteria, including staphylococci, streptococci, and vancomycin-susceptible strains of *E. faecalis*. Daptomycin is available in an intravenous formulation. It is not approved for use in children, and pediatric experience with the drug is limited. Daptomycin should not be used for the treatment of pneumonia because it is inactivated by pulmonary surfactant.²⁷⁴

Considerable published experience exists now with daptomycin therapy (alone and in combination with other agents) in adult patients with VRE bloodstream infections, although pediatric data remain limited. Half (11 of 22) of the adult patients with VRE bacteremia or endocarditis treated with daptomycin summarized in three early reports were cured.^{157,231,265} Subsequently anecdotal reports have been published documenting successful treatment of VRE bacteremia or endocarditis with daptomycin alone or in combination with other agents.⁵ Higher doses of daptomycin (e.g., 8 mg/kg per day in adults) may be more effective for the treatment of bacteremia caused by VRE (and other bacteria). A number of retrospective comparisons have failed to identify significant differences in the outcomes of VRE bacteremia treated with daptomycin or linezolid.^{61,296} At least one meta-analysis, however, has shown a small but statistically significant increase in mortality among adults with VRE bacteremia treated with daptomycin compared to those treated with linezolid.¹² The published pediatric experience is limited, and clinical trials in children are under way. Based on pharmacokinetic studies, children may require higher doses of daptomycin (8 to 10 mg/kg in children 2 to 6 years old) to achieve comparable serum levels to adults with 4 to 6 mg/kg dosing.¹

Daptomycin resistance remains uncommon among enterococci²⁵¹ but may develop during therapy. Patients being treated with daptomycin should be monitored for the development of muscle toxicity by serial measurement of serum creatine kinase concentrations and screening for muscle pain or weakness.

The streptogramin antibiotic quinupristin-dalfopristin¹⁷² was approved by the FDA in September 1999 for the treatment of adults with infections caused by VREF. This agent is not approved for the treatment of *E. faecalis* infections, nor for pediatric use.

Quinupristin-dalfopristin has been reported to effect clinical cures of several serious infections caused by multiresistant *E. faecium*, including ventriculoperitoneal shunt infections in two patients,^{209,296} an infected aortic graft in one patient,²⁵⁴ and VREF peritonitis in a series of adults.¹⁷⁴ Clinical response to quinupristin-dalfopristin has been reported in approximately 74% to 80% of patients with VREF bacteremia.^{95,105,163,165,179,191,301,313} The lack of a consistent bactericidal effect may limit the utility of this agent in the treatment of endocarditis and other life-threatening infections. Quinupristin-dalfopristin therapy generally has been tolerated fairly well in both adults and children, although a high rate of venous phlebitis in recipients has led to a recommendation that the agent be administered through a central venous catheter. Myalgias and arthralgias are other commonly reported side effects of this agent. The potential utility of quinupristin-dalfopristin for the treatment of pediatric patients is limited by its venous toxicity, its lack of a consistent bactericidal effect against VREF, and its lack of clinically useful activity against *E. faecalis*.⁵⁷

Tigecycline is a novel glycylcycline antibiotic derived from minocycline. It is FDA approved in adults for treatment of complicated skin and soft tissue infections and abdominal infections caused by susceptible bacteria, including vancomycin-susceptible *E. faecalis*. It is active in vitro against both vancomycin-susceptible and vancomycin-resistant *E. faecalis* and *E. faecium*, but the clinical experience with this agent for treatment of VRE infections is limited and mostly consists of case reports involving combination antimicrobial therapy.^{5,31} Pediatric experience is even more limited.¹³¹

Several other promising new antibiotics with in vitro activity against VRE isolates are being studied in clinical trials, including the lipoglycopeptides oritavancin and telavancin,¹⁸⁸ as well as new members of the oxazolidinone and streptogramin classes of antibiotics.

PREVENTION OF ENTEROCOCCAL INFECTIONS

The explosive increase in nosocomial infections caused by vancomycin-resistant and multiantibiotic-resistant enterococci^{37,77} has rendered prevention of enterococcal infections, particularly those caused by VRE strains, a public health priority in the United States.^{40,99,207,236,267} In 1995, the Hospital Infection Control Practices Advisory Committee (HICPAC) recommended a series of overlapping strategies designed to prevent the development of serious VRE infections.²³⁶ These strategies remain useful today and are designed to simultaneously reduce vancomycin resistance in enterococci and prevent nosocomial infections caused by these organisms. Implementation of such strategies has been reported to reduce or eliminate the transmission of VRE organisms in health care facilities.²²² However, overall rates of nosocomial infection by VRE continued to increase in the United States from 1995 to 2004, perhaps because the HICPAC guidelines were followed inconsistently.⁴⁰ (See the CDC website http://www.cdc.gov/ncidod/dhqp/pdf/ar/ICU_RES_Trend_1995-2004.pdf.)

Reversing the Trend Toward Vancomycin and Multiple-Antibiotic Resistance in Enterococci

The use of vancomycin^{236,267} and treatment with broad-spectrum antibiotics, including the third-generation cephalosporins and carbapenems,^{77,107,182,199,205,213,243} are risk factors for colonization and the development of infection with VRE strains. Consequently the HICPAC and CDC recommend that all hospitals, even those at which VRE organisms have not been isolated, should (1) develop a comprehensive antimicrobial utilization plan, (2) oversee surgical prophylaxis, and (3) develop institution-specific guidelines for the proper use of vancomycin.²³⁶ These strategies are echoed in the recommendations for development of antimicrobial stewardship programs that have been made jointly by the Society for Healthcare Epidemiology of America, the Infectious Diseases Society of America (IDSA), and the Pediatric Infectious Diseases Society.²⁷⁷

Efforts to eliminate unnecessary use of vancomycin are of critical importance^{236,267} but may be inadequate unless the use of other classes of antimicrobials is reduced as well (see later discussion). In 1995, HICPAC provided recommendations regarding the acceptable and appropriate use of vancomycin (Box 84A.2), as well as recommendations

BOX 84A.2 Situations in Which Vancomycin Use Is Appropriate or Acceptable

Treatment

- Treatment of serious infections caused by β -lactam-resistant, gram-positive microorganisms
- Treatment of gram-positive infections in patients with serious allergies to β -lactams
- Treatment of antibiotic-associated colitis only when it fails to respond to metronidazole or is severe and potentially life threatening

Prophylaxis

- Endocarditis prophylaxis after certain procedures in high-risk patients according to the American Heart Association guidelines
- Prophylaxis for major surgical procedures involving implantation of prosthetic materials or devices (single-dose prophylaxis usually is adequate)

Modified from Recommendations for preventing the spread of vancomycin resistance: Recommendations of the Hospital Infection Control Practices Advisory Committee (HICPAC). *MMWR Recomm Rep*. 1995;44(RR-12):1–13.

BOX 84A.3 Situations in Which Vancomycin Use Should Be Discouraged

Treatment

- Empiric therapy for febrile neutropenic patients (unless there is presumptive evidence of an infection caused by gram-positive organisms, such as a Hickman catheter exit-site infection, and the local prevalence of methicillin-resistant *Staphylococcus aureus* strains is substantial)
- Treatment of an isolated, single blood culture positive for coagulase-negative *Staphylococcus*
- Treatment (chosen for dosing convenience) of infections caused by β -lactam-susceptible, gram-positive microorganisms in patients with renal failure
- Continued empirical use of presumed infection in patients whose cultures are negative for β -lactam-resistant gram-positive microorganisms
- Primary treatment of antibiotic-associated diarrhea
- Eradication of methicillin-resistant *S. aureus* colonization

Prophylaxis

- Routine surgical prophylaxis except in patients with life-threatening allergy to β -lactams
- Systemic or local prophylaxis for infection of indwelling intravascular catheters
- Routine prophylaxis for infants with very low birth weight
- Routine prophylaxis for dialysis patients
- Use of vancomycin solution for topical application or irrigation
- Selective decontamination of the gastrointestinal tract

Modified from Recommendations for preventing the spread of vancomycin resistance: Recommendations of the Hospital Infection Control Practices Advisory Committee (HICPAC). *MMWR Recomm Rep*. 1995;44(RR-12):1–13.

regarding situations in which vancomycin use should be discouraged²³⁶ (Box 84A.3). These recommendations remain useful, but the emergence of community-acquired MRSA infections^{120,126,144} has resulted in increased empirical and definitive use of vancomycin for an HICPAC-approved indication: “treatment of serious infections caused by β -lactam-resistant, gram-positive microorganisms.”²³⁶

In addition, efforts should be undertaken to reduce the unnecessary use of broad-spectrum antibiotics and certain agents with potent

antianaerobic activity, particularly in settings with high rates of nosocomial infection (such as ICUs). These efforts are necessary because many studies indicate that nonglycopeptide antibiotics also exert selective pressure for VRE strains and that limitation of the use of vancomycin alone has only a modest effect on reducing VRE colonization and infection.²⁴³ Exposure to agents with broad-spectrum activity (but lacking antienterococcal activity), such as the extended-spectrum cephalosporins, appears to predispose to colonization with VRE organisms,^{74,243} whereas exposure to antimicrobials with potent antianaerobic activity (even if they are also active against enterococci) may promote high-density, prolonged VRE colonization (by eliminating gut anaerobes that may interfere with colonization by VRE strains).^{73,233,243}

Preventing and Controlling the Spread of Nosocomial Infection by Vancomycin-Resistant Enterococci

The increasing prevalence of *Enterococcus* in nosocomial infections is related to the intrinsic and acquired antimicrobial resistance of these organisms, but the factors leading to increased antibiotic resistance in enterococci are not identical to those that predispose to enterococcal colonization, infection, or both. Enterococcal infections are concentrated increasingly in debilitated and immunocompromised patients, including those with malignancies, recipients of bone marrow and solid organ transplants, burn victims, premature neonates, and critically ill patients with indwelling intravascular catheters. Consequently special attention should be paid to potential outbreaks of VRE infection in hospital wards caring for these high-risk patients.⁴⁰

Efforts to prevent the spread of VRE colonization, infection, or both probably will be more successful if the VRE isolates are confined to a few patients in a single area of the hospital. Widespread colonization with VRE strains may precede identification of infections by these organisms. Therefore all hospitals should implement active VRE surveillance and formulate a multidisciplinary plan to prevent nosocomial spread of VRE strains if such organisms are identified. In hospitals that have not isolated VRE strains, periodic antimicrobial susceptibility testing should be performed on enterococcal isolates from all sources, particularly from high-risk patient populations such as those in intensive care or transplant units. If VRE organisms are identified, a comprehensive plan to prevent nosocomial spread of these bacteria should be instituted immediately. The HICPAC guidelines summarized the essential elements of such a plan.²³⁶ Hospital infection control staff and clinical staff must be notified promptly when VRE strains are isolated from a clinical sample, and isolation precautions should be implemented immediately to prevent patient-to-patient transmission of VRE organisms. These precautions include gown and glove isolation, vigorous hand washing, dedicated use of noncritical patient items such as thermometers and stethoscopes, and prompt surveillance of any possibly exposed patients for VRE colonization. Additional measures may be necessary in hospitals with endemic or continued VRE transmission despite implementation of the aforementioned measures.²³⁶ Ostrowsky and colleagues²²² reported that an active infection control program that included surveillance cultures and prompt isolation of infected patients successfully reduced the spread of VRE strains in health care facilities throughout the Sioux land region of Iowa, Nebraska, and South Dakota.

Once VRE organisms become endemic in a hospital unit, achieving complete eradication is very difficult. The duration of VRE colonization in individual patients may be weeks or months,^{40,197} although spontaneous resolution of colonization occurs frequently.^{40,196} Attempts to eradicate colonization in individual patients generally have been unsuccessful.^{40,196} Consequently the measures recommended by HICPAC and others are directed at preventing the initial establishment of VRE strains in hospitals. Implementation of these policies will require the involvement of hospital pharmacy and therapeutics committees, quality assurance programs, and medical staff. Ongoing monitoring of the efficacy of these programs is necessary.

84B ■ Viridans Streptococcal Infections

J. Chase McNeil

VIRIDANS STREPTOCOCCAL INFECTIONS

The group of *Streptococcus* species characterized as viridans, α -hemolytic, or oral streptococci is ubiquitously present on the human oral mucosa. These organisms are important pathogens in children and adults alike; they cause infections ranging from caries and bacterial endocarditis in immunocompetent hosts to fatal sepsis in neutropenic persons.

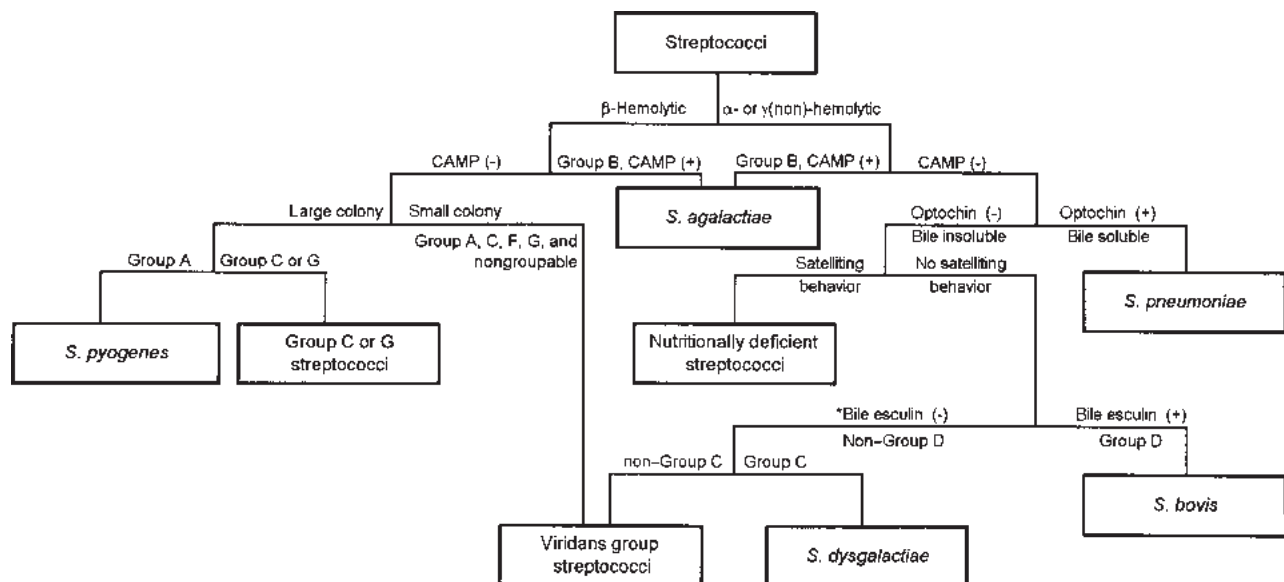

None of the terms applied to this group is entirely satisfactory. Not all members of the α -hemolytic streptococci are α -hemolytic, some being γ -hemolytic (nonhemolytic) or even β -hemolytic. Furthermore *Streptococcus pneumoniae*, which is α -hemolytic, is not considered a member of the viridans group. The term “viridans streptococci” is likewise inadequate, because “viridans,” derived from the Latin *viridis* (green), refers to the sheen caused by partial hemolysis around α -hemolytic colonies on sheep blood agar. The term “oral streptococci” circumvents the dilemma of outliers in the hemolytic classification schema; however, viridans streptococci are found in sites other than the oral cavity, and nonviridans streptococcal species are frequently present in the oral cavity. In accordance with the American Society for Microbiology’s most recent guidance,²⁷³ the term “viridans streptococci” is used here for this diverse group of bacteria, with the understanding that member organisms are typically but not invariably α -hemolytic. We further note that viridans refers not to a species of streptococci but rather to a group of species, notwithstanding erroneous references to *Streptococcus viridans*.²⁹⁷

Streptococci have been reclassified on the basis of molecular and genetic studies^{66,273}; however, this reclassification may cause clinical confusion for the short term. For example, certain small-colony β -hemolytic streptococci, including some in Lancefield group A, are now considered to be viridans streptococci. The hope is that classification based on molecular similarities will eventually lead to a clearer understanding of the infectious diseases associated with these organisms. One should recognize, however, that the current knowledge of viridans streptococcal infections is based predominantly on studies of the α -hemolytic members of the viridans group.

MICROBIOLOGY

Streptococci are gram-positive, catalase-negative bacteria that are spherical or ovoid and less than 2 μm in diameter. They are facultatively anaerobic and nonmotile and do not produce spores or gas. Some strains require an atmosphere enriched with carbon dioxide (5%). The enterococci (distinguished by their ability to grow in 6.5% sodium chloride) and lactococci (formerly Lancefield group N streptococci) were previously classified as streptococci but have now been assigned to separate genera.

Fig. 84B.1 is a classification schema for the clinically important streptococcal species. Hemolysis of blood agar remains a key tool for classifying streptococci. Strains that are β -hemolytic are further characterized according to colony size and Lancefield group (a serologic

classification system based on cell wall carbohydrate). Group B *Streptococcus agalactiae* strains can typically be identified by β -hemolysis and a positive Christie, Atkins, and Munch-Peterson (CAMP) test result²⁷³; however, some strains of *S. agalactiae* that are α - or γ -hemolytic also produce a positive CAMP test result.

Large-colony, β -hemolytic, group A streptococci make up the species *Streptococcus pyogenes*. Most other large-colony, β -hemolytic streptococci are group C or G streptococci, and they are occasionally pathogenic. Among the α - or γ -hemolytic streptococci, *S. agalactiae* (group B streptococci) and *S. pneumoniae* are generally identified by positive CAMP and Optochin test results, respectively. Bile solubility confirms an Optochin-susceptible isolate as *S. pneumoniae*; however, some *Streptococcus mitis* isolates (as determined by genetic sequencing) yield similar results.¹⁷⁸

Nutritionally deficient streptococci are identified by their requirement for the presence of a second bacterial species (*Staphylococcus aureus* is typically used in testing) to maintain growth on agar. These streptococci will generally grow in blood culture media in the absence of reduced nicotinamide adenine dinucleotide produced by a second bacterial species and may demonstrate some growth on agar in the absence of other bacteria. Nutritionally deficient streptococci were once classified as viridans streptococci, but more recent studies have assigned these organisms to a new genus: *Abiotrophia adjacens* and *Abiotrophia defectiva*.¹⁶⁴ With the exception of *Enterococcus* spp., streptococci that are α - or γ -hemolytic, possess Lancefield group D antigen, and are bile esculin positive may be tentatively identified as *Streptococcus bovis*. This species was once considered a viridans streptococcus but is now classified separately.

Strains of one species of group C streptococci, *Streptococcus dysgalactiae*, are α - or γ -hemolytic. These strains must also be distinguished from the viridans group. A species once included in the viridans group, *Streptococcus morbillorum*, was reclassified as *Gemella morbillorum*.¹⁶⁷

The *S. anginosus* group, sometimes referred to as the *S. milleri* group, includes *S. anginosus*, *S. constellatus*, and *S. intermedius*. These can be either β -hemolytic or nonhemolytic, often have small colonies, and may belong to any number of different Lancefield groups (A, C, G, F, or un-typeable). The *S. anginosus* group can be distinguished from other β -hemolytic streptococci based on a positive Voges-Proskauer reaction.¹⁰⁴ These organisms are often grouped together with viridans streptococci (and will be discussed briefly later); however, they truly have a different taxonomic classification.

The remaining streptococcal organisms may tentatively be identified as viridans group streptococci. Thus, in practice, viridans streptococci continue to be characterized by the absence of features that distinguish

other major streptococcal pathogens. Viridans streptococci have no characteristics that can be used to definitively confirm their identity in the standard microbiology laboratory.

Classification of species within the viridans streptococci group has also been challenging. Several schemata have been developed over the years, including those of Carlsson,⁴⁸ Coleman and Williams,⁶² Facklam,¹⁰³ Ruoff and Kunz,^{271,272} and Coykendall.⁶⁶ However, each of these schemata lacks reliable markers for member species, and clinical isolates are inconsistently classified as a result. Consequently efforts to characterize the clinical features of infections according to individual viridans streptococcal species have been largely unsuccessful. Molecular and polymerase chain reaction (PCR)-based taxonomies have been used to classify viridans streptococci,^{5,66,232,270,359} but these techniques are generally unavailable in the clinical laboratory. Given the current flux in the taxonomy of these organisms, the American Society for Microbiology has advocated a simplified, practical approach to classifying viridans streptococci (Table 84B.1).²⁷³ The biochemical tests available in many clinical microbiology laboratories can be used to assign clinical isolates to one of the five groups to which the 14 clinically important viridans streptococcal species belong. Rapid molecular nucleotide sequence analysis and PCR-based tests are available for tentative identification of individual viridans streptococcal species.^{110,121,239,272,323} However, precise identification of species currently has clinical significance only as an epidemiologic tool.

EPIDEMIOLOGY

Viridans streptococci are the predominant oral microflora of humans; they are also commonly found in other areas of the upper respiratory tract, throughout the gastrointestinal tract, and in the female genital tract. Viridans streptococci are occasionally identified as skin flora.

Viridans streptococci begin colonizing neonates shortly after birth. By 1 month of age, virtually all infants are colonized with at least one species of viridans streptococci.²³⁶ The mix of colonizing species varies with human ontogeny. For example, *Streptococcus mutans*, a species implicated in the development of caries, is rarely found in preeruptive children but is commonly present after the eruption of teeth.^{50,90,321} The ecology of other viridans streptococcal species also appears to be affected by the eruption of teeth.^{51,90,299,321} In addition to these temporal factors in the colonization of infants and children, individual viridans streptococcal species preferentially colonize certain anatomic areas of the oral cavity and pharynx. For example, *Streptococcus sanguis* is the predominant isolate of the buccal mucosa but is rarely found on the dorsum of the tongue, where *S. mitis* is the predominant species.¹¹⁴ Diet may also

TABLE 84B.1 Simplified Classification Schema for Viridans Streptococci

Group	Species	Hemolysis	Sorbitol	Arginine	Voges-Proskauer	Mannitol	Esculin

Data from Coykendall AL. Classification and identification of the viridans streptococci. *Clin Microbiol Rev*. 1989;2:315–28; and Ruoff KL. *Streptococcus*. In: Murray PR, Baron EJ, Pfaller MA, et al, eds. *Manual of Clinical Microbiology*. 6th ed. Washington, DC: American Society for Microbiology; 1995:299–307.

affect viridans streptococcal ecology. For example, the low oral pH that can result from consumption of sugar-containing beverages and other carbohydrates favors colonization with caries-producing *S. mutans*.^{129,318}

Little is known about the transmission of viridans streptococci in general, but studies have shown that *S. mutans* is commonly transmitted within families, especially from mother to child, and among young school children.^{4,47,82,136,274} Toothbrushes may be an important vehicle of transmission of viridans streptococci in children.¹⁹³ A normal dishwasher cycle eliminates *S. mutans* from toothbrushes.²² The hands of hospital personnel, especially those with skin disorders such as eczema, may also be a vehicle for transmission.⁵⁹ In addition, paper dental records have been suggested as a vehicle for the transmission of viridans streptococci.⁶⁸

Viridans streptococci play an important role in the ecology of the oral flora by protecting against potentially more invasive pathogens via colonization resistance.^{21,119} This mechanism was demonstrated by a double-blind study in which patients who had completed antibiotic therapy for group A streptococcal pharyngitis were treated with either a preparation containing four species of viridans streptococci or a placebo. None of the 17 patients in the treated group experienced recurrence of group A streptococcal pharyngitis, whereas pharyngitis recurred in 7 (37%) of the 19 patients in the placebo group.²⁶³ A second double-blind, placebo-controlled multicenter trial by the same group confirmed these findings.²⁶⁴ Viridans streptococci may also contribute to colonization resistance to pathogens such as methicillin-resistant *S. aureus* in the infant oral cavity³³⁷; nontypeable *Haemophilus influenzae*, *S. pneumoniae*, and *Moraxella catarrhalis* at the eustachian tube orifice³²⁰; and *Neisseria gonorrhoeae* in the female genital tract.²⁰³ In addition to competing for mucosal adherence sites, viridans streptococci produce hydrogen peroxide and bacteriocins that inhibit certain competing bacteria; this mechanism may also contribute to colonization resistance.^{69,71,338,343} Conversion of the hydrogen peroxide to ozone in the oral cavity may play a role in colonization resistance to other bacterial species and to *Candida* species.³³⁶

PATHOGENESIS

Viridans streptococci are typically low-virulence organisms; when they do cause infection, it is usually nonpyogenic with the exception of infections caused by the *Streptococcus anginosus* (*milleri*) subgroup. They are implicated most often in localized infections of the sinuses and oral cavity, including the teeth, after the tissues are directly invaded by colonizing organisms. Caries is a dental disease that develops during a period of years, often in association with *S. mutans* infection interacting with other oral flora.¹⁷¹ Patients with cystic fibrosis may be particularly susceptible to caries because of a decreased buffering capacity.⁴⁹ Viridans streptococci are associated with a variety of gingival diseases, possibly including gingival hyperplasia accompanying chronic phenytoin administration. In an experimental animal model, phenytoin-induced gingival hyperplasia was more advanced in rats infected with *Streptococcus sobrinus* than in uninfected control animals.²²⁰ On occasion, viridans streptococci, usually organisms of the *S. anginosus* subgroup, cause pyogenic infections, including abscesses in the brain, lung, and abdomen. An intriguing preliminary study suggested that viridans streptococcal-related dental disease is associated with the subsequent development of coronary artery disease.¹⁸⁵ Viridans streptococci are among the microorganisms isolated from atherosclerotic plaque, although their role in the pathogenesis of atherosclerosis is unknown.⁵⁷ Typically viridans streptococci cause life-threatening infection only when the oral mucosa is disrupted and the host's mechanisms of microbial clearance are compromised by conditions such as neutropenia or cardiac valve disease.

It is the preponderance of viridans streptococci in the oral flora, rather than their virulence, that accounts for their predominance in infections originating in the mouth. In a study of 36 children who underwent extraction of normal or abscessed teeth, 11 (30%) had postextraction positive blood cultures, and viridans streptococci were exclusively isolated in all 11.³⁰⁶ Bacteremia occurred more commonly after removal of diseased teeth (37%), but it also occurred after removal of normal teeth (23%). In a small study, children with dental caries had a higher burden of *S. mutans* in the saliva than those children

without caries, suggesting that the relative proportion of oral species play a role in dental pathology.²²⁴

Another study of 58 children who underwent dental extraction included 26 who received penicillin, amoxicillin, or erythromycin prophylaxis because of a risk of endocarditis.⁶⁵ Bacteremia was detected in only 9 (35%) of the 26 children who received prophylaxis and in 20 (63%) of 32 children who did not ($P < .05$). In this study, viridans streptococci accounted for 37% of the blood isolates, strict anaerobes accounted for 26.5%, and a variety of organisms accounted for the remainder. The number of colony-forming units per milliliter of blood ranged from 2 to 12. Even within a single colony-forming unit, more than one bacterial species was sometimes identified after subculture.

In a study from Spain, bacteremia was detected in 96%, 64%, and 20% of patients 30 seconds, 15 minutes, and 1 hour after dental extractions, respectively.³³⁰ This study indicates that bacteremia after dental procedures may not be as transient as was generally believed.

A study of 30 subjects with chronic periodontitis and 30 subjects with periodontal health showed that 40% and 41% had bacteremia during dental flossing; viridans streptococci were the most common isolate in both groups.⁶⁷ Roughly half of positive subjects remained positive 10 minutes after flossing.

Although these two studies differed in the diversity of organisms isolated, both indicated that viridans streptococci are the organisms most likely to invade the blood after trauma to the oral cavity. Viridans streptococcal bacteremia also occurs commonly during orthodontic banding¹⁰² and esophageal stricture dilation, also reflecting the predominance of these organisms in the oral and salivary flora.³⁶⁵

The ability of viridans streptococci to bind to oral mucosa, dental surfaces, and dental plaque by interaction with specific microbial and host "receptors" accounts for the preferential colonization of the oral cavity by these organisms.³⁴¹ This interaction also helps explain the localization of the various viridans streptococcal species to distinct anatomic sites as well as the involvement of ontologic factors in colonization. The precise nature of bacterial adherence to the oral mucosa is not defined but appears to involve streptococcal lipoteichoic acid.¹⁴⁶ Through release of modulin protein I/II, viridans streptococci induce the expression of adhesion molecules such as E-selectin and intercellular (ICAM-1) and vascular cell (VCAM-1) adhesion molecules on endothelial cells, promote transendothelial migration of neutrophils in vitro, and induce cytokine release in epithelial (interleukin-6 [IL-6]) and endothelial (IL-6 and IL-8) cells.^{345,346} Orthodontic appliances favor the proliferation of *S. mutans*.³³² The host's immune status also may be an important determinant of adherence and subsequent invasion. For example immunocompetent persons produce secretory IgA to *S. mutans*,¹³ and these antibodies are capable of preventing caries in a rodent model.²¹² Viridans streptococci within the biofilm present in dental plaque are at least 500 times more resistant to antibiotic treatment than is predicted on the basis of their susceptibility in culture medium; this finding suggests that antibiotic treatment cannot eradicate viridans streptococci from dental plaque, even temporarily.¹⁷³

At the University of Texas M. D. Anderson Cancer Center in Houston, the incidence of viridans streptococcal bacteremia increased extraordinarily between 1972 and 1989, from one to 47 cases per 10,000 admissions.⁹³ A risk factor analysis indicated that patients were significantly predisposed to the development of bacteremia by prophylactic administration of TMP-SMX or a fluoroquinolone, profound neutropenia, or the administration of antacids or histamine type 2 receptor antagonists.⁹³ Presumably, administration of the implicated antibiotics and antacids favored the overgrowth of viridans streptococci and their proliferation throughout the gastrointestinal tract, which in turn would favor viridans streptococcal bacteremia in an immunocompromised host, especially a neutropenic host whose mucosal barrier was disrupted by cytotoxic chemotherapy. Notably although administration of cytosine arabinoside (cytarabine, Ara-C) was identified as a major risk factor for viridans streptococcal sepsis in many other studies,^{34,35,45,84,152,198,209,257} it did not emerge as a risk factor in this study. In a recent Canadian study, a higher cumulative dose of cytarabine was associated with viridans streptococcal bacteremia in children with acute myelogenous leukemia, although this was not associated with streptococcal septic shock per se.¹⁸¹

The ability to adhere to damaged cardiac valves and vegetations is a key factor in the pathogenesis of viridans streptococcal endocarditis. Strains of viridans streptococci carried by healthy children adhered less well to buccal and endocardial cells than did strains isolated from children with viridans streptococcal endocarditis.^{283,284} Lipoteichoic acid is thought to help mediate adhesion of viridans streptococci to endocardium, and the effectiveness of penicillin prophylaxis may reflect its reduction of lipoteichoic acid on the bacterial cell surface.¹⁸⁷

The ability of antibiotics to alter the surface properties of bacteria, even those resistant to the bactericidal action of the drug, may be an important determinant of the effectiveness of prophylactic antibiotics.^{187,295} In the host, fibronectin is an important determinant of viridans streptococcal binding to damaged endothelium. Although viridans streptococci do not bind to soluble fibronectin, a reactive fibronectin binding domain becomes available when the fibronectin molecule is immobilized, as in endocarditis.¹⁸⁶ Mutant viridans streptococci that were unable to bind to fibronectin were shown to be significantly less virulent in an animal model of endocarditis.¹⁸⁶

The ability of viridans streptococci to induce platelet aggregation also may be a factor in the pathogenesis of endocarditis.^{111,194} In viridans streptococci-challenged, anticoagulated rabbits, only microscopic vegetations developed despite fulminant sepsis, indicating inability to limit the infection. In contrast, viridans streptococci-challenged, nonanticoagulated animals tended to have large vegetations and a subacute course.¹⁴⁹ These findings are concordant with those of a separate study showing that the density of bacteria within vegetations was greater in viridans streptococci-challenged thrombocytopenic rabbits than in nonthrombocytopenic control animals; these results suggest that platelets limit progression of the disease.³¹⁴ Surprisingly neutropenia appears to have little effect on susceptibility to endocarditis in animal models, although it impedes containment of the infection.^{207,208}

In neutropenic cancer patients and those who have undergone bone marrow transplantation, viridans streptococci cause septic shock and adult respiratory distress syndrome (ARDS). Viridans streptococci also induce nephritis in experimental models.^{6,325} Little is known about the mechanisms involved in the pathogenesis of these conditions. Viridans streptococci produce no endotoxin, and no specific exotoxins have been identified. Nonetheless products of these organisms can activate complement²¹⁸ and induce production of tumor necrosis factor- α (TNF- α) and TNF- β , IL-1, IL-2, IL-6, IL-8, interferon- γ , and nitric oxide.^{23,98,138,202,230,301,303,317} Strains isolated from patients with sepsis were found to induce TNF- β and IL-8 production more potently than colonizing strains isolated from healthy subjects.³⁰⁴ A study of two neutropenic patients with fatal viridans streptococcal sepsis showed high blood levels of IL-6, especially late in the course of infection, whereas levels of IL-1 and TNF- α were unremarkable.⁹⁶ Viridans streptococcal lipoteichoic acid induces production of cytokines and nitric oxide in vitro,^{98,218} but the clinical significance of these observations is not known. Unlike blood-borne group A streptococci isolated from patients with septic shock, viridans streptococci isolated from the blood of pediatric cancer patients with septic shock do not express superantigens in vitro.²²⁸ Thus intravenous immune globulin, which has been suggested as an adjuvant therapy for group A streptococcal shock, may not be effective in cases of viridans streptococcal sepsis.

CLINICAL MANIFESTATIONS

The viridans streptococcal species are diverse, and consequently the infections they cause show a variety of clinical manifestations. Typically the viridans streptococci cause nonpyogenic infections such as bacteremia and endocarditis, whereas the *S. anginosus* group tends to cause invasive pyogenic infections, including bone infections, brain abscesses, appendicitis, and pulmonary and abdominal abscesses.²²¹

Sepsis in Immunocompromised Hosts

For obscure reasons, the relative incidence of gram-positive bacterial infections, especially viridans streptococcal infections, has increased in immunocompromised hosts during the past 2 or 3 decades. Viridans streptococci were first identified as an important cause of sepsis in neutropenic patients with cancer in 1978, when 29 episodes were reported

in adults and children at the National Cancer Institute²⁴³ and six episodes were reported in children at the M.D. Anderson Cancer Center.¹⁴⁵ The significance of blood isolates of viridans streptococci in the setting of cancer had previously not been generally appreciated. The fact that no deaths occurred in the original National Cancer Institute series or in a subsequent series from that institute²⁶⁸ suggested that viridans streptococci produce a benign bacteremia similar to that caused by coagulase-negative staphylococci. In contrast, three of the six children at M. D. Anderson died. Several other centers in Europe and North America have reported fulminant, sometimes fatal viridans streptococcal sepsis in patients with cancer and in patients who have received transplants.* Overall, the reported death rate associated with viridans streptococcal sepsis has ranged from 0% to 50%; most centers report mortality rates of approximately 10%. In some centers, viridans streptococci are the most common cause of fatal and nonfatal sepsis.^{26,34,128,135} The incidence of viridans streptococcal sepsis appears to be higher in children than in adults.^{201,310} In a study from St. Jude's Children's Research Hospital from 1983 to 2008, viridans streptococci accounted for 63 of 702 (8.9%) bloodstream isolates from children with cancer.²⁰⁴ In a recent Italian study of both adults and adolescents who underwent hematopoietic stem cell transplantation, viridans streptococci accounted for 8% of bloodstream infection posttransplant with an 8% 30-day mortality.²¹⁴

The oral cavity is the most common portal of entry in immunocompromised hosts. Catheter-related viridans streptococcal bacteremia is unusual as determined by quantitative culture of simultaneous peripheral and catheter blood specimens. However, because administration of antacid is a risk factor,⁹³ the lower gastrointestinal tract is likely to be a portal of entry in some patients taking antacids and potentially in other circumstances. Several factors predispose patients to viridans streptococcal sepsis. Profound neutropenia is clearly a predisposing factor,^{34,93} although viridans streptococcal bacteremia occasionally develops in cancer patients with absolute neutrophil counts greater than 1000/mm³. Mucositis, especially oral mucositis, is a well-recognized risk factor.^{34,35,93,128,198,209} Cytarabine appears to incur a risk even greater than that caused by its induction of clinically apparent mucositis,^{34,35,45,84,97,152,198,209,257} although this greater risk has not been observed in at least one study.¹²² Chemotherapy does markedly alter the oral flora, with 25 species identified only after chemotherapy in one study.²²² The use of prophylactic TMP-SMX or quinolones is also an important risk factor.^{34,35,60,93,108,128,238} The observation that administration of acyclovir may decrease the incidence of viridans streptococcal bacteremia in transplant patients suggests that herpes simplex virus infection may be a risk factor as well.²⁵⁸ Allogeneic bone marrow transplantation has also been associated with increased risk of viridans streptococcal sepsis, which increases the mortality rate by a factor of 4.¹⁹⁸ Development of viridans streptococcal sepsis has also been observed to be associated with menstruation.⁹³

The hallmark clinical feature of viridans streptococcal sepsis in an immunocompromised host is fever that typically is high, coincides with neutropenia and mucositis, and frequently lasts for several days after viable organisms are cleared from the blood. Most patients recover uneventfully. However, fulminant septic shock may occur. Shock may appear early, although it is often delayed for 2 or 3 days after the onset of sepsis, and it occurs despite prompt sterilization of blood by effective antibiotics.³¹⁰ ARDS frequently occurs in severe cases, usually 2 or 3 days after the initial bacteremia.^{12,93,322} Focal complications, including pneumonia, encephalopathy,²⁸⁰ and meningitis, are uncommon. Rash and palmar desquamation may be present but are not common.⁹³ For unexplained reasons, the incidence of aspergillosis is increased after viridans streptococcal sepsis in children with cancer.²²⁹

Several studies have implicated *S. mitis* as a more pathogenic species of viridans streptococci that has a greater likelihood of causing shock and ARDS in patients with cancer,^{12,35,61,88,137,205,310,322} but other studies have found no clear relationship between clinical features and species.⁹³ *S. mitis* is the closest known relative of *S. pneumoniae*, and the two species share numerous pathogenicity genes.⁷⁵ Investigators at M. D. Anderson Cancer Center used multilocus sequence analysis to classify

*References.12, 15, 26, 34, 35, 45, 61, 63, 93, 128, 131, 140, 151, 174, 198, 201, 238, 255, 257, 294, 302, 310, 349.

viridans streptococci into species and investigate associations with severity of illness. *S. mitis/oralis* species were more often associated with a severe bacteremia phenotype even when correcting for the presence of neutropenia.²⁹³ *S. mitis* isolated from cancer patients with sepsis has also been found to be more antibiotic resistant than other species of viridans streptococci isolated from the same patient population.¹³⁷

Neonatal Sepsis, Meningitis, and Other Infections

Viridans streptococci are normal inhabitants of the female genital tract and are a common cause of chorioamnionitis and subsequent abortion.¹⁰ They are also a frequent cause of neonatal sepsis and meningitis.^{2,30,40,115,182,219,352} Viridans streptococci do not ordinarily colonize the skin of newborns and should not entirely be dismissed as contaminants when they are isolated from normally sterile sites.² At some newborn centers, the incidence of bacteremia and meningitis caused by viridans streptococci has approached or exceeded that caused by group B streptococci, although viridans streptococcal infections tend to be less severe.^{40,219} *Streptococcus oralis* (*S. mitis*) caused more than half of the cases in one study.³⁵² The portal of entry of the organism is generally unknown in this setting, but a fetal scalp electrode was implicated in one case.¹¹⁶ Unusual manifestations in newborns include pharyngitis and epiglottitis,³⁷ endocarditis,²⁰⁶ and conjunctivitis.¹⁷⁰ Viridans streptococci also account for 6% to 12% of community-acquired bacteremias, with a higher prevalence in children than in adults.³¹⁹

Endocarditis

Viridans streptococci are a common cause of endocarditis at all ages because of the organism's ability to adhere to diseased endocardium and its frequent implication in bacteremia after dental procedures and routine mouth care. A study at a teaching hospital in Finland found that, starting in 1995, *S. aureus* overtook viridans streptococci as a cause of endocarditis.¹³⁹ A review of published series by Elder and Baltimore showed a shift in the microbiologic etiologies of endocarditis in children from viridans streptococci to *S. aureus* predominance in the modern era of surgical repair of congenital heart disease.⁹¹ However, a study in Minnesota found no significant change in the etiology of endocarditis between 1970 and 2000; viridans streptococci remained the most common cause.³²⁹ A study in Israel noted that *Candida albicans* was the most common cause of hospital-associated endocarditis in children, whereas viridans streptococcus was the most common cause of community-acquired endocarditis in children.¹⁹⁵ Viridans streptococci tend to cause subacute endocarditis; blood cultures may be only intermittently positive. *S. sanguis* and *S. mitis* are the species most commonly identified.^{85,253,259,315,354} Complications of viridans streptococcal endocarditis include septic pulmonary emboli, congestive heart failure, pericarditis, myocardial abscess, meningitis, osteomyelitis, and glomerulonephritis.^{172,253} Shock and ARDS occur in immunocompromised patients but uncommonly in immunocompetent patients with endocarditis.

Pneumonia

Pulmonary infiltrates frequently complicate viridans streptococcal sepsis in neutropenic hosts. In most cases, these infiltrates represent ARDS and not primary pneumonia. However, several cases of primary viridans streptococcal pneumonia have been reported in previously healthy persons.^{118,127,196,223,249,279} In some cases, the diagnosis was supported by multiple viridans streptococcus isolates from blood in the absence of endocarditis. The incidence of viridans streptococcal pneumonia may be significantly underestimated because tracheal isolates of viridans streptococci are usually discounted as contaminants, which they may not be in all cases.²⁶⁵ In children with *S. milleri* group pleuropulmonary infections, computed tomography often shows complex pleural effusion and lung abscesses, which may require drainage for optimal treatment.¹⁷⁷ Viridans streptococci are increasingly recognized as contributing to pulmonary infections in children with cystic fibrosis (CF), a population with a higher prevalence of antibiotic resistance among viridans streptococcal isolates.^{130,233,298} The presence of certain viridans streptococci may augment the virulence of an epidemic strain of *Pseudomonas aeruginosa* among CF patients in an airway biofilm model.³⁵⁵ Given the increasing incidence of viridans streptococcal infection and the escalating prevalence of antibiotic resistance among these organisms, clinicians

should consider viridans streptococci as potential causes of pneumonia when they are isolated in the absence of other pathogens.

Osteomyelitis and Septic Arthritis

Viridans streptococci are unusual causes of osteomyelitis and septic arthritis. Extension of an oral infection into the mandible or maxilla is the most common cause of viridans streptococcal osteomyelitis,²³⁵ but several cases of vertebral osteomyelitis caused by these organisms have been described.^{3,44,74,269,339,350} Infection of the long bones^{227,256} and septic arthritis¹⁷ occur infrequently.

Caries

Although caries was recognized as an infectious disease in 1890 by workers trained in Robert Koch's laboratory, its infectious nature is still not accepted universally.^{9,14,89} Evidence that *S. mutans* is the main cause of caries in children and adults alike is substantial,^{9,14,38,290,324,335,342} but other viridans streptococci, *Lactobacillus* spp., and *Actinomyces* spp. also have cariogenic potential among the more than 700 species found in the indigenous microflora.^{162,251,290,342} *S. mutans*, which colonizes the oral cavity only after the eruption of teeth, has a predilection for the dental surfaces, metabolizes sucrose, and produces a strong acid that weakens the mineral matrix of teeth, allowing the organisms to penetrate the dental structure.^{52,290} Fluoridation of the water supply has been credited with strengthening tooth enamel, thereby fostering resistance to the harsh acids produced by *S. mutans*.²⁹⁰ Fluoride exerts potent antibacterial activity against *S. mutans*, particularly at low pH.^{52,344} Thus fluoridation of water supplies may represent, albeit in a unique form, the most widespread and successful use of antibacterial prophylaxis. Topical treatments also provide protection against the cariogenicity of *S. mutans* and in some circumstances depend on the antibacterial action of fluoride.^{144,328,340,363} Short courses of oral antibiotics can substantially reduce colonization with *S. mutans* and may be an important adjunct to the treatment of caries.³⁰⁹ Specially designed culture systems are available to detect and measure the concentration of *S. mutans* in plaque to monitor the effects of therapy.^{38,351} Because the development of cavities typically requires a few years of infection, there is ample opportunity to interrupt the pathogenesis of this disease.⁹ Meticulous attention to teeth brushing and dental hygiene can reduce the burden of *S. mutans* in the oropharynx of preschool-aged children in one randomized clinical trial, but the effect was short lived.¹⁸⁴ A study in Germany showed that a special long-term program begun during pregnancy and continued through the teenage years increased caries-free dentitions from 57% in the control group to 90% in the treatment group.²¹⁰

Abscesses and Other Infections

Suppurative infections produced by viridans streptococci are typically caused by the *S. anginosus* (formerly *S. milleri*) group: *S. anginosus*, *S. constellatus*, and *S. intermedius*. Like *S. aureus*, members of this group resist killing by polymorphonuclear leukocytes and stimulate less chemotaxis than other viridans streptococci do.³⁴⁸ *S. anginosus* is particularly prevalent in odontogenic abscesses, subdural empyemas, and epidural abscesses.^{134,300} Because *S. anginosus* inhabits the upper respiratory tract and the gastrointestinal tract and is relatively invasive, this organism causes sinusitis; otitis media; meningitis; and abdominal, splenic, and perianal abscesses. It is also often identified in brain abscesses, sometimes in association with tongue piercing.* *S. anginosus* group organisms may infect the brain through a hematogenous route that originates in the oral cavity or intestinal tract or by direct invasion through the upper respiratory tract. In a recent series from Paris of children with sinogenic intracranial infections, the *S. anginosus* group were the most commonly isolated pathogens.¹²⁰ Furthermore *S. anginosus* is associated with more frequent need for neurosurgical intervention and long-term neurologic deficits.⁷⁷ Molecular analysis indicates that some cases of culture-negative intracranial abscess are caused by the *S. anginosus* group.²⁴⁰ Similarly these organisms may be emerging pathogens in orbital cellulitis/abscesses in children, being the most common cause in a study from the University of Colorado.²⁸⁶ Sepsis is uncommon with these purulent infections in non-neutropenic patients, usually occurring in association with an intraabdominal source.^{190,276}

*References 29, 64, 95, 141, 176, 213, 217, 221, 276, 311.

Other unusual infections caused by viridans streptococci include a large outbreak of *S. mitis* pharyngitis accompanied in 50% of cases by a toxic shock-like syndrome.¹⁸⁹ Meningitis resulting from both hematogenous and direct spread has been observed in healthy adults.¹⁸⁸ Iatrogenic meningitis due to contamination by oral viridans streptococci may complicate lumbar puncture or other central nervous system procedures.^{100,282,360} Lung abscesses caused by viridans streptococci may result from the aspiration of saliva.^{158,249} Empyema and mediastinitis are other reported thoracic infections associated with viridans streptococci.^{24,158} Myositis complicated by rhabdomyolysis in children with leukemia has been reported.²⁷⁷ Viridans streptococci also are found occasionally in liver abscesses,^{20,112,123} peritonitis,²⁸ appendicitis,²⁴⁴ and endophthalmitis.⁵⁵ In solid organ transplantation patients, viridans streptococci are a common cause of cholangitis.³¹²

DIAGNOSIS

Infections caused by viridans streptococci cannot be distinguished clinically from those caused by other gram-positive and gram-negative bacteria. Collection of adequate culture specimens is essential for diagnosis. Viridans streptococcal infections are typically diagnosed by culture of blood or other normally sterile tissues. The organisms may be present in low concentration. A volume of 30 mL of blood has been suggested as the optimal volume for culture in an adult-sized patient.²⁸⁹ The addition of agents that neutralize the antibacterial effects of fresh blood, such as sodium polyanethol sulfonate, significantly improves the yield of blood cultures.²⁸⁸ Chemotherapeutic agents may interfere with detection of viridans streptococci in blood.²³⁷ Viridans streptococci have been reported to cross-react with *S. pneumoniae* omnisera, potentially causing false-positive results.¹⁴⁸

ANTIBIOTIC SUSCEPTIBILITY

Viridans streptococci were once considered universally penicillin susceptible. Today, however, penicillin-resistant and penicillin-tolerant viridans streptococci are identified worldwide as causes of sepsis, endocarditis, meningitis, and other infections, including conjunctivitis of the newborn, making knowledge of specific antimicrobial susceptibility more important.* Penicillin resistance occurs commonly, particularly in patients receiving long-term penicillin therapy,^{8,32,234,307,313} although even short courses of antibiotics may predispose patients to colonization with resistant viridans streptococci.^{101,124,216} Monthly injections of penicillin do not appear to increase penicillin resistance in oral viridans streptococci.³¹ In a study of more than 732 viridans groups streptococci bloodstream isolates from the M. D. Anderson Cancer Center, more than 50% were nonsusceptible to penicillin, and nonsusceptibility to third- and fourth-generation cephalosporins and meropenem was seen almost exclusively when the penicillin MIC was 2 µg/mL or greater. In a multivariate analysis, β-lactam nonsusceptibility was independently associated with nosocomial onset of infection, use of a β-lactam antibiotic as prophylaxis, and receipt of a β-lactam in the previous 30 days.²⁹² Antibiotic resistance is found more commonly in viridans streptococci isolated from children compared with adults, perhaps reflecting greater use of antibiotics in children.⁸⁰ Infection with penicillin-resistant viridans streptococci is associated with a higher risk for mortality than is infection with penicillin-susceptible strains.^{79,305} All species of viridans streptococci may develop antibiotic resistance, although *S. mutans* rarely exhibits resistance.¹⁵⁷ Investigators from Seoul examined 1448 clinical isolates of viridans streptococci for antimicrobial resistance. The proportion of isolates nonsusceptible to penicillin is 40.2% of *S. sanguinis*, 60.3% of *S. mitis*, and 78.9% of *S. salivarius*.⁵⁸ By contrast, only 6.2% of the members of the *S. anginosus* group were penicillin-nonsusceptible.

Resistance to a variety of antibiotic classes has developed during the past 2 decades,²⁴⁷ although resistance is still uncommon in community residents who have not had recent antibiotic treatment.³⁶¹ Resistance to cephalosporins is widespread; the general pattern of susceptibility is that cefotaxime and ceftioxime are usually more active than cefepime and cefuroxime, which are both more active than ceftazidime and

cephalexin.^{81,197,241,356} Previous cephalosporin therapy is a risk factor for cephalosporin resistance, an observation particularly relevant to patients with cancer.^{42,165} Resistance to fluoroquinolones, especially ciprofloxacin and ofloxacin, is common.^{54,72,78,11,281,359}

Levofloxacin has greater activity against viridans streptococci than the older fluoroquinolones do, and the newer agents garenoxacin, gatifloxacin, and moxifloxacin have enhanced activity against most gram-positive pathogens, including viridans streptococci.^{260,261,262,300} However, resistance develops rapidly when patients receive prophylactic quinolones, including levofloxacin and moxifloxacin.^{248,326} At the Mayo Clinic in Rochester, Minnesota, 6 (16%) of 37 transplant patients receiving levofloxacin prophylaxis developed viridans streptococcal sepsis (3 experienced shock); blood isolates were resistant to levofloxacin and to gatifloxacin and moxifloxacin.²⁵⁴ Resistance was associated with mutations in the quinolone resistance-determining region of GyrA or ParC. In the M. D. Anderson study, more than 70% of isolates were fluoroquinolone nonsusceptible.²⁹² Resistance of viridans streptococci to aminoglycosides,¹⁶³ tetracycline,^{72,81,359} TMP-SMX,^{72,78,81,359} clindamycin,^{78,333,359} erythromycin,^{39,72,78,352,353,359} other macrolide antibiotics,⁷ and vancomycin²⁹⁶ has also been reported. Meropenem resistance of viridans streptococci appears to increase in children with cancer who receive multiple courses of empirical therapy.¹ Isolates of *S. anginosus* have been identified with resistance to vancomycin mediated through a vanG element closely related to that seen in *E. faecalis*³⁰⁸; thankfully, however, such isolates remain extraordinarily rare.

The penicillin resistance of viridans streptococci appears to involve chromosomally mediated alterations in the organisms' penicillin-binding proteins.^{252,364} Initially researchers suspected that genes conferring penicillin resistance had been acquired from *S. pneumoniae*.⁸⁷ Subsequent studies, however, indicated that penicillin resistance may have evolved first in *S. mitis* and that *S. pneumoniae* might have acquired genes mediating penicillin resistance from this and other closely related viridans streptococcal species,^{53,86,246} although a recent study favors the other pathway.¹⁵³ Quinolone resistance determinants are also transmitted efficiently between viridans streptococci and *S. pneumoniae*,¹⁵⁶ and the *mef(E)* gene, which confers resistance to macrolides, is readily transmitted from viridans streptococci to *S. pyogenes*.¹⁶⁰

The clinical impact of the development of penicillin resistance among viridans streptococci has been far reaching. The emergence of penicillin-resistant viridans streptococci may in fact be encouraging the development of vancomycin-resistant enterococci because of the increased use of vancomycin to prevent and treat viridans streptococcal infection in patients with cancer.

Overall vancomycin is the antibiotic most reliably active against viridans streptococci. Teicoplanin also has been used successfully to treat viridans streptococcal endocarditis.³⁵⁷ Daptomycin, dalbavancin, quinupristin/dalfopristin, tigecycline, and linezolid are active in vitro against most clinical isolates of viridans streptococci,^{107,159,168,215,275} although breakthrough septic shock due to resistant *S. anginosus* has been reported during daptomycin therapy,²³¹ and 43% of viridans streptococci were resistant to quinupristin/dalfopristin in a study from Finland.¹⁸³

TREATMENT

Empirical antibiotic therapy for viridans streptococci should be based on the pattern of antibiotic susceptibility among recent local clinical isolates. Antimicrobial susceptibility testing of viridans streptococcal isolates is necessary. Limited data indicate that antibiotic susceptibility testing performed with the E-test is well correlated with agar dilution susceptibility testing.²⁶⁶ Although vancomycin-resistant clinical isolates are rarely identified at present, inclusion of vancomycin in susceptibility testing is advisable. For infections other than endocarditis and meningitis, single-antibiotic therapy is usually preferred. However, in neutropenic patients with cancer, restricting antibiotic therapy to drugs active against gram-positive bacteria may increase the risk for gram-negative bacterial infections.²⁴² Some investigators have advocated reserving vancomycin for neutropenic patients with shock or ARDS,³³³ whereas others have advocated inclusion of vancomycin in initial empirical therapy for patients with fever and neutropenia.^{94,294} The IDSA guidelines for the

*References 36, 41, 92, 106, 126, 147, 170, 180, 245, 252, 334.

management of fever and neutropenia in patients with cancer recommends only including vancomycin empirically in patients with specific risk factors for gram-positive infections including cellulitis, severe mucositis, hemodynamic instability, pneumonia, or suspected catheter-related bloodstream infection.¹¹⁷ Viridans streptococcal sepsis may occur in neutropenic patients despite ongoing antibiotic therapy with β -lactam agents to which the organisms are susceptible in vitro²⁹⁴; however, this phenomenon has not been observed during vancomycin therapy, thus supporting the use of this antibiotic for viridans streptococcal sepsis in neutropenic patients. In addition, various methods to measure the susceptibility of viridans streptococcus to various antibiotics commonly yield discrepant results.¹⁹¹

Combination therapy is often advocated for treatment of viridans streptococcal endocarditis^{33,113,200,347} and may be considered for treatment of meningitis, especially when the pathogen is penicillin tolerant.⁹⁹ A combination of either penicillins and aminoglycosides or of vancomycin and aminoglycosides is used most commonly. Penicillin and vancomycin are thought to increase the uptake of aminoglycosides, thereby providing synergistic bactericidal activity.³⁶² However, a meta-analysis of five clinical trials failed to identify any overall improvement in the outcome of patients with endocarditis who were treated with β -lactam and aminoglycoside combination therapy versus β -lactam monotherapy.¹⁰⁵ The 2015 AHA guidelines for the management of endocarditis¹⁶ recommend 4 weeks of intravenous penicillin G or ceftriaxone for native valve endocarditis secondary to viridans streptococci susceptible to penicillin (MIC ≤ 0.12 $\mu\text{g/mL}$). An alternative to this regimen in patients with good renal function and uncomplicated endocarditis is a 2-week course of penicillin or ceftriaxone both, along with gentamicin. This recommendation is based on data showing similar outcomes in select patients treated with monotherapy for 4 weeks compared to combination therapy for 2 weeks.²⁸⁷ For prosthetic valve endocarditis secondary to penicillin-susceptible viridans streptococci, 6 weeks of penicillin or ceftriaxone are recommended with the optional addition gentamicin for the first 2 weeks. In the case of prosthetic valve endocarditis from penicillin-resistant streptococci, the combination of a β -lactam and gentamicin are recommended for 6 weeks. Vancomycin monotherapy has been successfully used to treat patients with penicillin-resistant viridans streptococcal endocarditis^{150,169}; monotherapy with linezolid²²⁶ or ceftriaxone^{169,291} has also been used successfully.

Frequent dosing of antibiotics is generally recommended. However, because viridans streptococci exposed to combinations of penicillin or cephalosporin plus aminoglycoside appear to be susceptible to a postantibiotic effect,^{46,166,175} longer dosing intervals may be satisfactory, although data are currently insufficient to support a recommendation. The duration of therapy for viridans streptococcal infections other than endocarditis has not been studied but can generally be guided by site-specific practice and individual clinical response.

In the treatment of endocarditis, penetration of antibiotics into the fibrin vegetation may be markedly impeded. Viridans streptococci produce an exopolysaccharide composed predominantly of dextran, which may limit penetration. Experimental studies indicate that the extent of exopolysaccharide production by viridans streptococcal strains affects the success rate of antimicrobial therapy.²⁵⁰ Administration of dextranase to animals with experimental viridans streptococcal endocarditis enhances antibiotic efficacy, consistent with this observation.²¹¹ In the future, such adjuvant therapies designed to reduce the size or density of valvular vegetations may offer promise for patients with endocarditis who are not helped by conventional antibiotic therapy.

Another setting in which adjuvant therapy may be considered is viridans streptococcal sepsis in neutropenic patients who have received cytarabine chemotherapy. One uncontrolled trial suggested that the early addition of high doses of corticosteroids to the antimicrobial therapeutic regimen may reduce the incidence of associated ARDS and death.⁸³ However, data are insufficient to recommend this approach routinely.

PREVENTION

Attempts to prevent viridans streptococcal infection have focused on three distinct settings: prevention of caries, prevention of endocarditis,

and prevention of sepsis in neutropenic patients with cancer. Efforts have been successful in the first two settings. However, the emergence of penicillin-resistant viridans streptococci and concern about the future emergence of vancomycin resistance highlight the need for new approaches to prevent infection with these ubiquitous organisms. In developing such methods, investigators should keep in mind that the resistance to colonization provided by viridans streptococci can protect the host from more virulent pathogens (see [Epidemiology](#)).

The incidence of caries in the United States has been sharply reduced by fluoridation of water supplies, inclusion of fluoride in toothpaste, and modification of diet (e.g., use of sugar substitutes). Fluoride acts as an antibacterial agent that also strengthens the resistance of teeth to invasion by bacteria. The use of dental varnishes, gels, and rinses that contain fluoride or other antibacterial agents such as chlorhexidine or vancomycin may be beneficial in selected cases.^{109,161,199,225} *Streptococcus salivarius*, a relatively nonpathogenic organism that produces potent bacteriocins, has been proposed for study as a probiotic.²⁷⁸ There is evidence for and against the use of xylitol gum to reduce the levels of *S. mutans* in the oral cavity.^{143,285}

The AHA has led a successful effort to prevent endocarditis by the administration of systemic antibiotic prophylaxis to patients with known endocardial defects who are undergoing dental procedures.⁷⁰ These efforts are aimed especially at preventing viridans streptococcal endocarditis, and penicillin is the antibiotic most commonly used. The mechanism or mechanisms by which antibiotic prophylaxis prevents endocarditis are not completely understood. In animals, endocarditis can be prevented by administration of bacteriostatic antibiotics and by maintenance of serum levels of bactericidal antibiotics that are well below the minimum inhibitory concentration for the colonizing viridans streptococci.¹²⁵ Vancomycin has been observed to prevent development of vancomycin-tolerant *S. sanguis* endocarditis in experimentally challenged animals without reducing the incidence or level of bacteremia; thus antibiotics may prevent endocarditis by reducing bacterial adherence to endocardium.²⁵ This hypothesis is supported by a study in which 21% of children receiving antibiotic prophylaxis developed bacteremia, in some cases with antibiotic-resistant organisms, but endocarditis rarely occurred.¹⁴² However, studies in animals have indicated that the probability of preventing endocarditis is related to the antibiotic susceptibility of the challenging streptococcal strains.¹⁴² A study from Sydney found that 11 of 30 patients undergoing dental scaling developed viridans streptococcal bacteremia after mouth rinsing for 2 minutes with normal saline, whereas none of 30 patients developed viridans streptococcal bacteremia after rinsing with 7.5% povidone-iodine.⁵⁶ A similar study of patients undergoing dental extraction showed a decreased duration of bacteremia if chlorhexidine mouthwashes were used prior to extraction.¹⁸ These studies provide promising alternatives for prophylaxis, given the increasing resistance to antibiotics found in oral flora.

Prophylaxis should be carefully targeted³³¹ and administered immediately before dental procedures. An increase in the number of blood-borne antibiotic-resistant viridans streptococci can be detected within 6 hours of antibiotic treatment and persists for 9 days or longer.¹⁷⁹ Experimental studies of the prevention of endocarditis by antibiotic administration after challenge with bacterial inocula have yielded inconsistent results,^{27,155,192} and the clinical utility of this approach is unknown. Topical treatment with vancomycin or chlorhexidine has been advocated as an adjuvant in preventing endocarditis, but its efficacy is unproved.^{316,358} In 2007, the AHA revised its guidelines on the criteria for antibiotic prophylaxis to prevent endocarditis making the criteria more restrictive in an effort to curb unnecessary antibiotic administration. Notably, this has not been associated with a rise in endocarditis cases, suggesting that indeed many more patients were being previously prescribed prophylaxis than was necessary.⁷⁶

In recent years, viridans streptococcal infections have presented a major problem in neutropenic patients with cancer and in patients who have received bone marrow transplants. Because penicillin-resistant viridans streptococci are widespread, some cancer centers include vancomycin in the initial empirical antibiotic regimen for febrile neutropenic patients.²⁹⁴ In addition, despite concern about promoting vancomycin resistance, bone marrow transplant physicians are administering intravenous vancomycin prophylactically to high-risk patients

in an effort to prevent viridans streptococcal sepsis; results of an observational cohort study support this practice.¹⁵⁴

Uncontrolled trials of oral vancomycin paste¹⁹ and vancomycin mouthwash⁴³ in children receiving cytotoxic chemotherapy suggested their efficacy in preventing viridans streptococcal infection. However, an increase in colonization and infection with vancomycin-resistant enterococci is a predictable consequence of increased vancomycin use. Therefore the CDC has recommended that empirical vancomycin therapy be avoided when it is feasible and encouraged investigators to explore alternatives to the empirical or prophylactic use of vancomycin.

In a comparative trial, penicillin prophylaxis was superior to TMP-SMX prophylaxis in preventing viridans streptococcal infections in patients with cancer, despite extensive colonization with penicillin-resistant streptococci.¹³³ In other studies, oral prophylaxis with penicillin or roxithromycin (a macrolide antibiotic) also appeared to reduce the incidence of viridans streptococcal infection in patients with cancer in comparison to historical controls.^{73,267,305} In contrast, prophylactic ampicillin did not reduce the incidence of viridans streptococcal sepsis in patients receiving autologous bone marrow transplants, and the incidence of penicillin resistance increased.³² Other penicillin prophylaxis trials have also observed increased penicillin resistance.³² The CDC does not recommend the routine use of penicillin prophylaxis in patients receiving bone marrow transplants.¹³²

Levofloxacin prophylaxis is currently commonly used to prevent bacterial infections in adults with cancer, but there is concern that viridans streptococci rapidly develop quinolone resistance.³²⁷ Among 45 children with acute myeloid leukemia cared for at Children's Hospital Los Angeles, ciprofloxacin prophylaxis was associated with a decline in bacteremia episodes from gram-negative bacteria but a subsequent increase in bacteremia due to gram-positive agents, largely viridans streptococci.¹⁰⁸ Innovative prophylactic methods and carefully designed clinical trials are needed to identify effective prophylactic measures, especially for patients at high risk, such as children undergoing chemotherapy for acute myeloid leukemia.

Pneumococcal Infections

Stephen I. Pelton • Michael R. Jacobs

RELEVANCE OF PNEUMOCOCCAL DISEASE TO CHILD HEALTH

The pneumococcus (*Streptococcus pneumoniae*) continues to be a leading cause of morbidity and mortality in persons of all ages. Its impact on child health is demonstrated by Elliott and Beeson's conclusion that it is one of the five pathogens that account for nearly half of infection-related deaths among children less than 5 years of age (Fig. 85.1)¹⁵⁴

Pneumococcal infections include serious diseases such as meningitis, bacteremia, and bacteremic pneumonia, as well as milder but more common illnesses, such as community-acquired pneumonia (CAP), sinusitis, and otitis media. The causative agent, *Streptococcus pneumoniae*, is found in the nasopharynx of 30% of children in high-income countries and as many as 80% of children in low-income countries.* The

*References 6, 18, 106, 119, 122, 160, 167, 191, 217, 332, 369, 380, 617.

FIG. 85.1 Pathogen-specific infection-related mortality among children <5 years. Among deaths from respiratory infection, 41% were attributed to *Streptococcus pneumoniae*. (From Elliott SR, Beeson JG. Estimating the burden of global mortality in children aged <5 years by pathogen-specific causes. *Clin Infect Dis*. 2008;46:1794–5.)

pneumococcus is transmitted mainly through respiratory droplets among children and to adult contacts and was estimated to cause nearly 500,000 global deaths annually among children less than 5 years of age in 2008 by the World Health Organization.⁵⁷⁷ Many children experience some form of pneumococcal infection (e.g., otitis media or pneumonia), but sepsis or meningitis occur in few. The continued incidence and severity of pneumococcal disease, coupled with significant case-fatality rates despite antimicrobial therapy and the increasing prevalence of strains of pneumococci resistant to antimicrobial agents, serve to underscore the necessity for ongoing surveillance and expanded research into treatment and prevention of pneumococcal infections.

Pasteur and Sternberg, working independently in 1880 and 1881, discovered the pneumococcus. Pasteur called the organism *microbe septicémique de la salive*, and Sternberg called it *Micrococcus pasteri*. Each researcher recovered pneumococci from rabbits injected with human saliva. Friedlander demonstrated pneumococci in tissue from humans with pneumonia in 1882 and, in the following year, found them in most cases of acute pneumonia. Friedlander described both the characteristic capsule and colonial morphologic features of pneumococci and, in 1884, recovered pneumococci from the blood of patients with pneumonia for the first time. During the next few years, pneumococci were found in virtually all types of infection, including meningitis and otitis media. By 1890, researchers had established the pneumococcus as the most common cause of acute pneumonia, at which point the term *pneumococcus* emerged. In addition, the pneumococcus became recognized as a principal cause of meningitis and other serious infections. In 1926, the pneumococcus was called *Diplococcus pneumoniae* because it usually appears in pairs. In 1974, it was renamed *Streptococcus pneumoniae* because it forms long chains when grown in liquid medium.

Early researchers immunized animals with cell-free filtrates of pneumococci, demonstrated that serum from immune animals could protect against experimental pneumococcal infection, deduced the role of immunity in promoting phagocytosis, and noted agglutination of pneumococci by serum from immune animals. In 1897, Pane treated humans suffering from pneumonia with serum from such animals. By 1900, researchers had laid the foundation for immunotherapy for pneumococcal pneumonia, the only effective treatment until the advent of chemotherapy. Investigators noted that agglutination of pneumococci appeared to depend on the strain isolated. In 1910, Neufeld and Haendel classified pneumococci into several discrete serotypes on the basis of the appearance of capsular swelling (the Quellung reaction). Only strains exposed to homologous serum showed capsular swelling. Their work made possible all subsequent epidemiologic investigations of pneumococcal infection, immunotherapy with type-specific serum, and the development of vaccines. The original classification of pneumococci

was limited to types I, II, III, and IV (others). Currently, 94 serotypes have been identified and certain serotypes have proved to be more virulent than others. Virulence depends, to some extent, on the species of animal infected.

The use of antisera for the treatment of pneumococcal pneumonia proved strikingly effective when type-specific sera were administered. As early as 1913, Cole and associates showed that treatment with antisera lowered fatality rates from 25% to 30% to 10.5%. In addition to allergic reactions, difficulties associated with this treatment included the necessity of identifying the causative serotype, the need for the earliest possible administration of antisera, and the availability of antisera to only types I, II, and III. White⁵⁹⁴ compared the efficacy of early antisera therapy and found that 403 of 1614 (25.0%) patients that did not receive any therapy died, while 32 of 377 (8.5%) who received therapy within 3 days of onset died and 24 of 127 (18.9%) who received therapy 4 or more days after onset died. Therapy with antisera had no beneficial effect on pneumococcal infections such as meningitis and endocarditis. Despite these drawbacks, the use of antisera soon became widespread. The advent of chemotherapy—first sulfa compounds, then penicillin—was followed by a precipitous decline in the use of antisera. Antimicrobial agents killed or inhibited pneumococci, regardless of serotype, and cured patients with previously incurable localized infections.⁵⁹⁴ Coincident with research resulting in the use of antisera came research into the efficacy of pneumococcal vaccines. Proof of efficacy lagged, and indisputable evidence of protection induced by vaccination was not available until 1945. The ability of pneumococci to cause epidemic pneumococcal pneumonia in young men crowded into army camps or gold mines allowed large-scale trials to be performed. Highlights of the development of effective vaccines include the trial of Wright and associates⁶⁰⁵ in South Africa beginning in 1911. Using a vaccine made with whole killed pneumococci, this trial produced inconclusive results. Many trials followed, with some showing trends toward protection. In 1923, Heidelberger and Avery²³⁷ published their classic article in which they stated that protective antibodies were reactive with surface capsular polysaccharides. In 1930, Francis and Tillett¹⁷⁸ showed capsular polysaccharides to be immunogenic for humans. Ekwurzel and colleagues¹⁵³ used a vaccine containing such polysaccharides during 1933 to 1937 and showed it to be effective. Smillie and associates used a preparation of serotype 1 polysaccharide to abort a hospital epidemic of pneumonia at State Hospital in Worcester, Massachusetts.⁵¹⁷

Although many of these studies suggested that specific pneumococcal polysaccharide antigens could confer protection against severe pneumococcal infection, not until 1945, in a trial performed on US Army and Air Force recruits, were they finally proved by MacLeod and associates to do so.³⁵⁶ This trial showed vaccination to be strikingly effective in preventing pneumococcal pneumonia caused by serotypes contained in the vaccine but not in preventing disease caused by other serotypes, thus showing serotype-specific protection.

Regrettably, interest in vaccination waned rapidly with the general availability of penicillin, and manufacturers voluntarily withdrew their vaccines from the market. This unfortunate attitude persisted for the next 2 decades until the inability of chemotherapy to prevent many deaths from pneumococcal disease was recognized.⁵³ The rapid development and spread of antibiotic resistance among many clinically important strains further emphasized that prevention could be more effective than treatment for pneumococcal disease. A few farsighted individuals continued to maintain surveillance of the serotypes causing human disease, and their work allowed the reintroduction of pneumococcal vaccines. The current status of vaccines is discussed later in this chapter. Interested readers should consult both White's *The Biology of Pneumococcus* and Heffron's *Pneumonia, with Special Reference to Pneumococcus Lobar Pneumonia*, as well as a comprehensive review by Watson and colleagues, for a complete account of the long and fascinating history of this organism.^{594,236,586}

EPIDEMIOLOGY

The incidence of pneumococcal disease is highest in children less than 2 years old and adults greater than 65 years of age and varies substantially by country, by individual health status, and by season. Prior to

FIG. 85.2 Incidence of invasive pneumococcal disease in children <2 years old in The Gambia and in various high- and low-risk populations. (From Greenwood B. The epidemiology of pneumococcal infection in children in the developing world. *Philos Trans R Soc Lond B Biol Sci.* 1999;354:777–85.)

introduction of pneumococcal conjugate vaccines for universal administration in young children, the highest rates were observed in infants, with a rapid decrease in incidence after 5 years of age. Greenwood reported that the incidence of invasive pneumococcal disease (IPD) in children under 2 years of age varies 10-fold—from less than 100 cases per 100,000 in Finland to more than 1000 per 100,000 in Australian Aboriginal children (Fig. 85.2).²¹⁴ In part, the variability reflects the increased risk among children with sickle cell disease or HIV, indigenous populations such as Native Americans, Inuit or Aborigine children, and malnourished children. However, as IPD impacts primarily healthy children, the susceptibility of high-risk groups contributes only slightly to the large geographical differences in incidence. Specific populations can have rates of IPD that are as much as 100-fold greater than age-matched healthy children residing within the same country. The incidence of IPD is also correlated with standard of living, with children in high-income countries having less disease than in low-income countries or less privileged populations. The incidence of IPD in children younger than 5 to 6 years in western Europe (e.g., Finland, the United Kingdom, Germany, Switzerland, Denmark, and Spain) was lower than 25 cases per 100,000 population per year in various studies; in Chile, Australia, and New Zealand, it was 25 to 60 per 100,000; and during the same period in the United States, the range was approximately 65 to 75 cases per 100,000.²³² The rates of IPD in US children appear to be atypical, with higher rates reported than in comparable high-income nations, although rates of pneumococcal meningitis appear more similar across countries.^{232,359} The difference in US incidence rates is most likely a reflection of the higher use of blood cultures in nontoxic febrile infants and toddlers in the United States than elsewhere.

Despite the increasing proportion of invasive pneumococcal disease among children with comorbid illness, the majority of cases occur in healthy infants and toddlers. Such children represent an immunologically naïve population susceptible to bloodstream invasion or direct invasion of the lower respiratory tract. Differences in the proportion of disease by age also vary globally. In The Gambia and comparable countries, a larger proportion of disease occurs in children less than 5 months of age compared with representative populations of US children (Fig. 85.3). Similarly, in many countries, colonization is more prevalent and begins earlier, usually in the first months of life, compared with industrialized countries.⁵

As virtually all children carry pneumococci belonging to several serotypes during their childhood, a focus on the epidemiology of carriage is warranted. In a study conducted in the United States, the prevalence of nasopharyngeal carriage in preschool children was 38% to 60% versus 29% to 35% and 9% to 25% in elementary school and junior high

FIG. 85.3 Age distribution of invasive pneumococcal disease in (A) young children in The Gambia and (B) high-risk and (C) low-risk communities in the United States. (From Greenwood B. The epidemiology of pneumococcal infection in children in the developing world. *Philos Trans R Soc Lond B Biol Sci.* 1999;354:777–85.)

school students, respectively.²³⁹ The prevalence in adults with no children at home was 6%. In studies in closed populations, such as kibbutzim in Israel or a poor and crowded community in southern Israel, the same differences between children and adults were noted.^{68,117} Contact with young carriers increases the carriage rates in older children and adults. In the United States, adults with no children living in the household had a carriage rate of 6%, whereas the carriage rate increased to 29% when children were present at home. Similarly, primary school-aged children who have siblings younger than 2 years old carried *S. pneumoniae* more often than did those without young siblings.³⁵³ In a study in Costa Rica, cultures in mother-child dyads showed an increased prevalence of carriage in infancy: from 6% at 1 month of age to 39% at 12 months of age. At the same time, carriage in mothers increased from 0% to 9.8%, thus supporting our understanding that pneumococci are transmitted from infants to adults—in this case, mothers.³⁷² In a Swedish study, the observed average duration of carriage was longer in children who had family carriers of the same serotype and, therefore, was suggestive of ongoing recirculation in the family.¹⁵²

Acquisition of *S. pneumoniae* may occur during the very first days of life. In infants aged 2 months, the prevalence of carriage ranges from less than 15% in most high-income countries to greater than 60% in low-income countries.¹⁸ Colonization peaks during the second and third year of life in high-income countries.^{122,213,238} The relationship of age to carriage is not understood, but it depends, at least in part, on the development of specific anticapsular antibodies.^{211,212} In toddlers vaccinated with a pneumococcal conjugate vaccine, nasopharyngeal acquisition of new *S. pneumoniae* vaccine serotypes was inversely related to serum levels of specific antipolysaccharide IgG antibodies.¹¹⁵ In another study, the presence of both circulating IgG and secretory immunoglobulin A (IgA) antibodies to the surface pneumococcal protein PsaA was associated with a lower prevalence of nasopharyngeal pneumococcal carriage.^{455,511} A 2004 study showed that mucosal anticapsular IgA developed in response to colonization in preschool-aged children, regardless of vaccination status.⁶⁶ This phenomenon has been hypothesized to contribute to the falling carriage rates observed with increasing age.⁶¹⁸ Potentially, maturation of innate immunity may also contribute to the declining prevalence of colonization with increasing age; however, a specific role or mechanism has not been established.

Crowding is an important factor that facilitates the spread of *S. pneumoniae*. Therefore, it is not surprising that in high-income countries the nasopharyngeal carriage rate and spread are highest in infants and toddlers attending daycare centers, with levels exceeding 90% in some studies, followed by those living with one or more siblings at home.^{18,122,448,568} In addition, the viral infections that are very prevalent in infants and toddlers attending daycare centers enhance colonization of the nasopharynx with *S. pneumoniae*.^{213,351,568} The combination of young age and increased incidence of respiratory viral infections renders daycare centers an important site for transmission of *S. pneumoniae* from child to child and subsequently child to parent or child to younger sibling.

The duration of carriage depends on age and serotype and may be related to additional factors, such as antibiotic treatment, immune status of the child, and unknown factors. Carriage lasts longer in infants and young toddlers than in older children and adults.^{116,152,211} Infants are colonized for an average of 30 days; however, carriage can persist for as long as 12 months in some.¹⁵⁰ In a study in the United States in adults, individual serotypes usually persisted for 2 to 4 weeks.

The relative risk for a specific serotype to colonize the nasopharynx of a child and its ability to cause respiratory or invasive infection appears to vary by serotype but not geographic location. Some serotypes—such as 6A, 6B, 9V, 14, 18C, 19A, 19F, and 23F—are among the most frequent colonizers in infants and young children in most parts of the world and thus often are considered “pediatric” serotypes.^{70,117} These serotypes are acquired frequently by infants and young children and often are carried for prolonged periods. After children reach the age of 2 years, carriage of these “pediatric” serotypes declines. Although pneumococcal carriage decreases overall with age, the proportion of “nonpediatric” serotypes increases with age. This phenomenon is demonstrated in Fig. 85.4.

In contrast to the “pediatric” serotypes, serotypes such as 1, 5, 7F, and 12 are carried infrequently and are eliminated from the nasopharynx rapidly. However, these serotypes are able to cause disease and even clusters or epidemics.^{70,117} The different distribution of serotypes among colonized children, children with invasive infections, and adults with pneumonia is depicted in Fig. 85.5.⁴⁹⁸

Although most colonization occurs without the development of disease, prospective, longitudinal studies have suggested that most systemic infections develop soon after colonization with a new pneumococcal serotype.^{160,209,211} Some carriers are protected from invasive disease by the presence of circulating antibodies. However, such antibodies do not always protect against invasion of contiguous sites. Other investigators have shown that a substantial number of pneumococcal otitis media cases occur at any time following nasopharyngeal colonization.⁵³⁴

The emergence of resistance to more than one antibiotic class has become a serious problem.²⁶⁶ In 1993, approximately a fifth of the pneumococcal strains in Iceland were penicillin nonsusceptible and 80% were multidrug resistant. When the risk for carriage of penicillin-resistant *S. pneumoniae* was investigated, a clear association was found not only with use of β -lactam drugs but also with the use of

FIG. 85.4 Nasopharyngeal carriage of *Streptococcus pneumoniae* in closed community living in crowded conditions in Southern Israel. *Pediatric serotypes 6A, 6B, 9V, 14, 18C, 19A, 19F, and 23F. (Modified from Dagan R, Gradstein S, Belmaker I, et al. An outbreak of *Streptococcus pneumoniae* serotype 1 in a closed community in southern Israel. *Clin Infect Dis*. 2000;30:319–21.)

FIG. 85.5 Distribution of selected serogroups/serotypes in *Streptococcus pneumoniae* isolates from adults with pneumonia, children with invasive pneumococcal disease, and nasopharyngeal specimens from sick children in Kenya. (Modified from Scott JAG, Hall AJ, Hannington A, et al. Serotype distribution and prevalence of resistance to benzylpenicillin in three representative populations of *Streptococcus pneumoniae* isolates from the coast of Kenya. *Clin Infect Dis*. 1998;27:1442–50.)

trimethoprim-sulfamethoxazole and erythromycin.²³ Following treatment of acute otitis media (AOM), carriage of trimethoprim-sulfamethoxazole-resistant *S. pneumoniae* was found in 23% of patients by day 6 and in 33% by day 40. Additionally, non-penicillin-susceptible *S. pneumoniae* was carried at these times by 26% and 43% of children, respectively. This remarkable promotion of colonization with penicillin-resistant strains by trimethoprim-sulfamethoxazole treatment occurred because many strains were resistant to both penicillin and trimethoprim-sulfamethoxazole.

The dramatic change in nasopharyngeal flora after initiation of antibiotic therapy has two important consequences. Antibiotic treatment not only can increase nasopharyngeal carriage of antibiotic-resistant *S. pneumoniae* but also can result in subsequent infection of the middle ear with that resistant strain within a few days.¹¹⁹ Second, the increased prevalence of antibiotic-resistant *S. pneumoniae* in the nasopharynx leads to enhanced transmission within extended families and daycare centers.^{122,191,238,448,474,609} The widespread use of antibiotics is likely to be responsible for the increase in antibiotic-resistant *S. pneumoniae*, especially in crowded populations such as daycare centers, thus creating a vicious cycle that is difficult, if not impossible, to overcome (Fig. 85.6).⁵⁶⁹

Since the use of pneumococcal conjugate vaccine has become widespread in the United States, the serotypes found most commonly

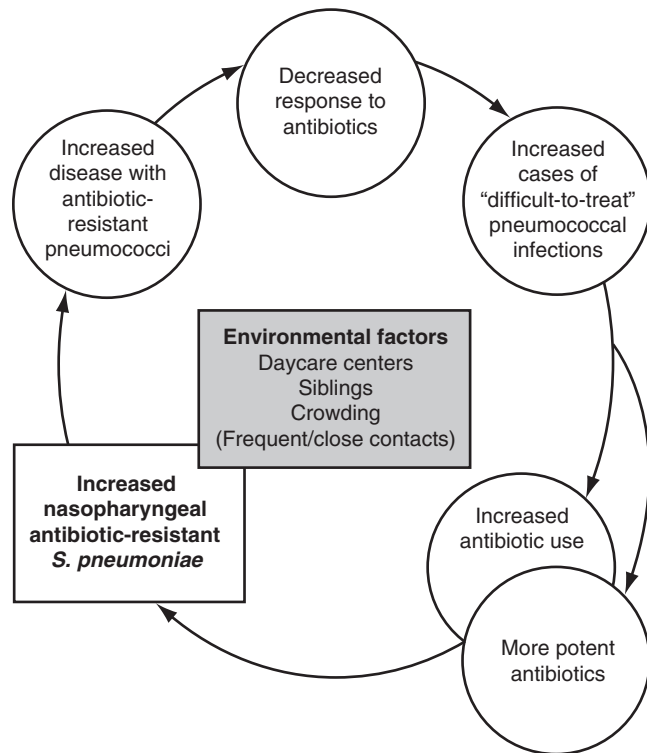

FIG. 85.6 Chain of events that creates a vicious cycle in which treatment with antibiotics increases nasopharyngeal carriage of antibiotic-resistant pneumococci, which decreases responsiveness to antimicrobial treatment. The decreased responsiveness results in use of more potent antibiotics, which continues the cycle.

in nasopharyngeal colonization have been replaced by nonvaccine serotypes. A study evaluating nasopharyngeal colonization in 16 Massachusetts communities during 2001 to 2004 showed a decrease in serotypes found in the 7-valent pneumococcal conjugate vaccine (PCV-7) from 36% to 14% along with an increase in non-PCV-7 serotypes from 34% to 55%.²⁵⁷ Another study showed that 25% of children colonized with pneumococci carried antibiotic-resistant, nonvaccine serotypes, including serotypes 19A and 35B, rarely detected before introduction of the pneumococcal conjugate vaccine. Further changes in the distribution of pneumococcal serotypes—specifically types 19A, 7F, and 6A—subsequent to the implementation of universal vaccination of children less than 5 years of age with the 13-valent pneumococcal conjugate vaccine (PCV13) has been observed.³⁵⁴ Both a reduction in overall carriage of the unique PCV13 serotypes and specific declines in serotypes 19A and 7F have been significant. The rapid decline in colonization with PCV13 led to a decline in prevalence of antibiotic resistance among pneumococcal isolates recovered from the nasopharynx.²⁹³ However, replacement pneumococcal strains (serotypes 6D, 15A, 15C, 16F, 23A, and 35B) have begun to acquire macrolide and/or β -lactam resistance.⁵⁵⁸ Pneumococcal serotype diversity among adults has been shown to be influenced by pediatric pneumococcal vaccination uptake.²⁰⁷ Analysis of differences in serotype proportions and incidence of adult IPD matching the 23-valent pneumococcal polysaccharide vaccine (PPSV23) and 13-valent conjugate vaccine showed that the median differential between the 23 and 13 serotypes increased from 16.3% to 24.4% ($P < .003$). This difference can be used to guide national recommendations for vaccine use in various populations.

Risk Factors for Pneumococcal Infection

Demographic Features

Age. Young age is a major risk factor for pneumococcal infection because of immunologic immaturity and the absence of acquired immunity. The relationship between age and the development of protective immunity to pneumococcal infection was published in 1932 by Sutcliffe and Finland.⁵³² Maternal antibody, passively transferred to the

fetus, protects against invasive infection in the first few months of life. These antibodies decay over the first few months and the incidence of invasive pneumococcal disease increases, peaking between 12 and 18 months of age, presumably as specific immunity is acquired following exposure. Following the introduction of pneumococcal conjugate vaccine (PCV), the peak incidence in children is now between 6 and 12 months of age.⁶¹² This age distribution reflects the ongoing susceptibility of young infants to nonvaccine serotypes due to naïveté of the infant immune system despite acquisition of protective antibody to vaccine serotypes following immunization.^{362,381,596} IPD in developing countries occurs earlier in life. It is hypothesized that this is related to earlier and more intense exposure to pneumococci in such children.⁶

Gender

In most studies of pneumococcal disease, there is a greater proportion of males than females. Yildirim reported that the proportion of male cases was significantly higher (58.5% vs. 41.5%; $P = .01$), but gender-specific incidence rates were not significantly different.*

Race/Ethnicity

Prior to the introduction of PCV, the incidence of pneumococcal bacteremia and meningitis in Alaskan Native children younger than 5 years ranges from 598 cases per 100,000 population in those 6 to 11 months of age to 56 cases per 100,000 population in those 36 to 47 months of age, which is approximately four times the incidence in similarly aged non-Alaskan Native/non-Native American children.¹³⁰ The highest incidence for any ethnic group in the United States is found in Navajo and Apache populations living on reservations in the southwestern United States. The incidence in children aged 1 to 2 years in these populations ranged from 557 to 2396 per 100,000.^{109,417} Among children younger than 5 years, the incidence of invasive pneumococcal disease in African American children in the United States was two to three times higher than that in white children of the same age.^{53,75,229,469} In a case-control study of risk factors for the development of invasive disease in young children, the association of race with disease risk was not statistically significant in an analysis that controlled for socioeconomic status.³⁴⁰ However, other studies have reported persistence of increased risk even when controlling for income.^{75,94,168,229,240} Whether environmental differences (e.g., poverty, use of wood burning stoves, crowding) completely explain the increased incidence in some populations in comparison to others in the United States or whether genetic differences are also contributory remains unclear. Universal immunization with PCV in children less than 5 years of age has resulted in a reduction in the incidence of invasive pneumococcal disease in Native Americans, African Americans, and other high-risk populations but has not completely eliminated differences in rates of disease, likely reflecting increased susceptibility to nonvaccine serotypes.⁵⁸⁷

In other geographic regions, differences among populations also can be observed, again being higher in populations that live in less privileged conditions. Such observations raise the question of the importance of genetic versus environmental risk factors. In southern Israel, the incidence of pneumococcal invasive infection during the first year of life in Bedouin infants (a population with a lifestyle, birth rate, and general disease incidence similar to that of low-income countries) was fourfold higher than in Jewish infants (a population with standards of living comparable to the middle/low social class in the high-income countries).¹⁸⁰

In New Zealand, when Maoris, Pacific Islanders, and others were compared, incidence rates of invasive pneumococcal disease in the first year of life per 100,000 population were 153, 276, and 52, respectively. These rates in children younger than 5 years were 67, 117, and 36 per 100,000, respectively.⁵⁷⁵

Seasonality

Pneumococcal infection occurs in a seasonal pattern with increased cases of invasive infections, pneumonia, and otitis media between September/October and April/May in the Northern Hemisphere, with the opposite picture in the Southern Hemisphere. Peak incidence often

*References 72, 147, 233, 376, 407, 425, 466, 506, 545, 612.

FIG. 85.7 Weekly rates of invasive pneumococcal disease in children (dotted line: birth to 17 years) and adults (solid line: >18 years) in the United States, 1996–98. (From Dowell SF, Whitney CG, Wright C, et al. Seasonal patterns of invasive pneumococcal disease. *Emerg Infect Dis.* 2003;9:573–9.)

occurs from December through February (Fig. 85.7).¹⁴⁶ The same seasonal variation in nasopharyngeal carriage of pneumococci is also observed with lowest rates in the summer months.^{213,351} This pattern is likely related to the seasonal variations in viral respiratory infections, which play an important role in increasing pneumococcal carriage and subsequent infection and in attendance at school and daycare centers. However, other factors are likely to be important. In one study, adults had higher incidence of pneumococcal disease following school holidays and presumably increased contact with children.⁵⁸³ In Israel, the Jewish and Bedouin populations in southern Israel demonstrate distinct and different seasonal patterns. The Jewish population appears similar to traditional Western populations with distinct seasonal variation. The Bedouin live in crowded and less hygienic conditions, with a high birth rate and a disease pattern similar to that in low-income countries, without a clear pattern of seasonality.³⁴² Recently, a subtle difference in the seasonal difference between bacteremia and pneumonia has been described in which bacteremic and nonbacteremic pneumonia peaked in winter (in Israel) while IPD peaked in the fall. The authors suggest these differences may imply differences in pathogenesis.⁵²

Lack of Breastfeeding

Breastfeeding may be protective against pneumococcal infection. The reduction in colonization and decreased attachment to pharyngeal cells is thought to be mediated through several components of the immune system, including secretory IgA, lactoferrin, and lysozyme. Some studies have suggested that breastfeeding protects against otitis media,¹⁹ but others have failed to show this effect.⁴⁸ Studies in the United States demonstrated a protective effect of breastfeeding against invasive pneumococcal infection in children in the general population⁴⁸ and in Alaskan Natives.¹⁹⁰ However, in Finland, no protective effect was observed.³³⁸

Crowding

Crowding contributes to many factors that increase the risk for acquiring pneumococcal infection, including viral infections, poor hygiene, and potentially increased person-to-person transmission of *S. pneumoniae*. Attendance at daycare centers was the most important risk factor for acquiring invasive pneumococcal infection in children and infants in several studies.* In a population-based, case-control study, adults aged 18 to 64 years who lived in households that included children attending daycare were at greater risk of acquiring invasive pneumococcal infection.⁴¹² In high income countries, attendance at daycare centers is also the most important risk factor for AOM, including pneumococcal otitis.^{406,478}

Immunocompromising Conditions

Congenital and Acquired Absence of Spleen or Splenic Function

The spleen is critical for the clearance of pneumococci from the bloodstream.^{531,584} Children in whom the spleen is absent or dysfunctional are at risk for the development of overwhelming pneumococcal infection (see clinical syndrome, sepsis, and purpura). In children with absence or dysfunction of the spleen, the mortality rate is multifold higher. Schutze and colleagues reported 27% mortality from prospective surveillance of eight US children's hospitals in children with splenic dysfunction.⁴⁹⁶ Splenic dysfunction is also regarded as explaining the increased incidence and severity of pneumococcal bacteremia in sickle-cell disease and other sickle hemoglobinopathies (e.g., hemoglobin sickle-cell disease or S- β -thalassemia).^{432,496,615} Children with hemoglobin sickle-cell disease, thalassemia, and other hemoglobinopathies demonstrate a higher incidence of IPD compared to healthy children, albeit lower than in persons with sickle-cell disease.^{327,554} Other factors that contribute to the high incidence and poor outcome for pneumococcal infection in persons with sickle-cell disease include low levels of circulating antibodies and complement deficiency.^{432,599} Penicillin prophylaxis is effective in reducing the risk of pneumococcal disease in children with absent or abnormal splenic function; however, the rate of disease remains increased compared to healthy children. PCV has been demonstrated to be immunogenic and effective in reducing disease due to vaccine serotypes in children with hemoglobinopathies (Fig. 85.8).^{8,223,570} However, increased rates of disease due to serotypes not contained in the current vaccines are observed.^{8,170,223,429,570,601,615}

Defective Antibody Formation

Reduced antibody formation is associated with increased risk of pneumococcal infection. Congenital agammaglobulinemia, acquired common variable hypogammaglobulinemia, and defective antibody production associated with diseases such as malignancies and human immunodeficiency virus (HIV) infection are associated with increased risk of pneumococcal disease.^{113,560} In the era preceding the introduction of highly active antiretroviral treatment, HIV-infected children had a 100-fold to 1000-fold increase in incidence compared to healthy children.^{16,55,162,179,360,388} In one study, the incidence of invasive pneumococcal disease was 6.1 cases per 100 patient-years in HIV-infected children through the age of 7 years.³⁶⁷ Despite the introduction of highly active antiretroviral treatment, HIV-infected African children remain a high-risk group for IPD and pneumococcal pneumonia.⁴¹¹

Neutropenia and Neutrophil Dysfunction

The risk of pneumococcal disease is not uniform across all neutrophil abnormalities. Primary and secondary neutropenia, such as cyclic neutropenia, drug-induced neutropenia, and aplastic anemia, are associated with an increased incidence of severe pneumococcal infection. However, the incidence is not increased in other granulocyte dysfunction syndromes, such as leukocyte adhesion deficiency syndromes.^{15,183}

Genetic Variation in Mannose-Binding Lectin

Approximately 5% of the population in Europe and North America and an even larger population in many developing countries are homozygous for mannose-binding lectin (MBL) codon variants. These subjects have a greater than 2.5-fold increased risk for the acquisition of pneumococcal infection than do those who do not have this variant or are only heterozygous for this variant.

Immunocompetent Conditions

Studies of IPD since the introduction of PCV in 2000 have identified that an increasing proportion of cases occur in children with comorbid conditions. Children over the age of 5 years with IPD were threefold more likely to have a comorbid condition compared to those less than 5 years old. Specific conditions identified by the Committee on Infectious Diseases of the American Academy of Pediatrics include children with chronic lung and heart disease, diabetes mellitus, cerebrospinal fluid leak, chronic renal failure and nephrotic syndrome (at least in part due to hypogammaglobulinemia), and cochlear implants are at increased risk for pneumococcal disease (Table 85.1). Children with asthma and

Incidence of invasive pneumococcal disease among individuals with sickle cell disease before and after the introduction of the pneumococcal conjugate vaccine. *Clin Infect Dis.* 2007;44:1428–33.)

TABLE 85.1 Underlying Medical Conditions That Are Indications for Pneumococcal Immunization Among Children, by Risk Group¹³

Risk Group	Condition
Immunocompetent children	Chronic heart disease ^a
	Chronic lung disease ^b
	Diabetes mellitus
	Cerebrospinal fluid leaks
	Cochlear implant
Children with functional or anatomic asplenia	Sickle cell disease and other hemoglobinopathies
	Chronic or acquired asplenia, or splenic dysfunction
Children with immunocompromising conditions	HIV infection
	Chronic renal failure and nephrotic syndrome
	Diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease; or solid organ transplantation
	Congenital immunodeficiency ^c

Modified from American Academy of Pediatrics. Pneumococcal Infections. Red Book: 2012 Report of the Committee on Infectious Diseases. In: Pickering LK, editor. Elk Grove Village, IL: American Academy of Pediatrics; 2012. pp. 571–582.

^aParticularly cyanotic congenital heart disease and cardiac failure.

^bIncluding asthma if treated with prolonged high-dose oral corticosteroids.

^cIncludes B- (humoral) or T-lymphocyte deficiency; complement deficiencies, particularly C₁, C₂, C₃, and C₄ deficiency; and phagocytic disorders (excluding chronic granulomatous disease).

neurologic conditions, including seizure disorders and muscular dystrophies, are also at increased risk. The risk is further increased in children with two or more comorbidities. In addition to increased incidence, children with such comorbid illnesses have poorer outcomes following IPD or pneumococcal pneumonia. Yildirim reported 2.5-fold greater rates of hospitalization and 3.7-fold higher case-fatality ratios for children with comorbid conditions.⁶¹¹

Pneumococcal Serotype

A characteristic of most disease-causing strains of *S. pneumoniae* is the presence of a polysaccharide capsule. The capsular polysaccharides are composed of repeating units of oligosaccharides, for most of which the exact chemical structure is known. To date, 94 distinct capsular types have been described, several very recently (Table 85.2). Understanding serotype distribution and characteristics is important for several reasons. First, a selected number of serotypes are responsible for the majority of disease. However, the serotypes vary somewhat by geography. For example, prior to the introduction of PCV, 7 serotypes (4, 6B, 9V, 14, 18C, 19F, and 23F) accounted for 80% of cases of IPD in North American children (Fig. 85.9A). Globally, a larger number of serotypes—including serotypes 1, 3, and 5—must be included to account for a similar 80% of IPD cases (Fig. 85.9B).³⁸² A significant positive association between disease and serotype has been demonstrated in children younger than 36 months, with serotypes 1, 5, and 12F associated with IPD, serotypes 1, 3, 5, 12F, 19A, and 19F with AOM, and serotype 3 with necrotizing pneumonia and nontypeable strains with conjunctivitis. A significant negative association with IPD was demonstrated for nontypeable *S. pneumoniae*. Understanding the distribution of serotypes causing serious pneumococcal disease is relevant to developing vaccine strategies for prevention and estimating the impact of a vaccine that provides coverage for a limited number of serotypes. Serotype distribution also

varies over time, as experience with serotype 1 disease in Europe demonstrated.

The serotype distribution of nasopharyngeal carriage and invasive and other pneumococcal diseases varies, as not all pneumococci have the same relative risk of progressing from carriage to disease. Invasive capacity, the term describing the relative risk of disease occurring following a colonizing event, appears to be an intrinsic property of pneumococcal strains, predominantly determined by the capsular polysaccharide. The invasive capacity for common serotypes has been computed by several investigators. Large differences among serotypes (>10-fold) have been reported and, in general, estimates of relative risk have been similar across studies. Dagan and colleagues were able to demonstrate that capacities to cause IPD and AOM were not comparable and that differences among serotypes were blunted for AOM compared to IPD (Fig. 85.10). Following the introduction of PCV7, investigators in many countries reported increases in both carriage and disease due to serotype 19A. In part, the increase in carriage resulted from intrinsic characteristics of specific clones of serotype 19A, permitting them to out-compete other serotypes; multidrug resistance, which allowed its persistence as a result of selective pressure from antimicrobial usage in the community; and the lack of significant cross-protection by antibodies generated in response to 19F capsular polysaccharide. It was initially hypothesized that including the capsular polysaccharide from serotype 19F in the vaccine would elicit cross-protective antibody against serotype 19A. The hypothesis was that antigenically related serotypes (those within serogroups)—for example, serotype 9A—would elicit cross-protective antibody against serotypes 9L, 9N, and 9V. However, although antibody to the 19A capsule increased following immunization with 19F as measured by enzyme-linked immunosorbent assay (ELISA), it was not sufficiently functional to prevent carriage or disease due to 19A following immunization with PCV7. Proof of cross-protection currently exists for antibody elicited by the 6B capsular polysaccharide, which demonstrates protection against disease and carriage due to

serotype 6A, as well as for 6A, which elicits protection against 6C strains.¹⁰⁸ For serotype 23F, an increase in carriage of the cross-reacting serotypes 23A and 23B has been observed following immunization with PCV containing 23F capsular polysaccharide. Insufficient data is available to understand whether capsular polysaccharides elicit cross-protection for other serotypes of the same serogroup. The extent of cross-reactivity between types within the respective serogroups may differ—for example, serotypes 6A and 6B have identical chemical composition except for one of the bonds between two sugars and are extensively cross-reactive, while types 19F and 19A are clearly less cross-reactive. Poolman suggested that the process of protein conjugation of the 19F polysaccharide during conjugation with CRM altered its structure such that antibody elicited was not functional against serotype 19A strains and that by using alternative strategies, such as employed for PCV10, greater functional activity against serotype 19A can be achieved.⁴⁴⁶ Another important reason for understanding serotype differences relates to clinical disease. Different serotypes may cause specific clinical syndromes. For example, serotype 3 is associated with necrotizing pneumonia, while serotype 1 is associated with empyema and “epidemic disease,” specifically in central Africa. Serotype 1 epidemiology also differs in that it causes disease across a broader age spectrum than the usual serotypes, which are primarily found in infants.^{42,189,566} High mortalities have been associated with specific serotypes as well.^{444,564,589} Serotype 1 is also linked to antimicrobial susceptibility. Prior to introduction of PCV7, the majority of antibiotic-resistant pneumococci were associated with five serotypes: 6B, 9V, 14, 19F, and 23F.

Other attributes beyond capsular polysaccharide also impact on clinical syndromes. Differences between strains of serotype 1 in Europe and Africa have been described. In Africa, disease due to serotype 1 is often meningitis and the strain is wild type with regard to the pneumolysin produced, whereas in Europe the clinical syndromes are bacteremia and pneumonia and the strain has a mutant pneumolysin, unable to produce hemolysis.^{383,589}

Evidence is clear that introduction of PCV13 has again impacted serotype distributions in the nasopharynx and in pneumococcal disease syndromes. Epidemiologic studies highlight differences in carriage by geographic locations that have major relevance as to whether replacement disease is more or less observed. For example, in France, serotypes with high invasiveness—such as 24F, 22F, 33F, and 15A—are more prevalent in carriage (than prior to PCV13 introduction) and appear to be increasing in invasive pneumococcal disease cases as well, suggesting that replacement disease will remain a challenge but likely vary by geography.⁵⁶⁷ Additional changes in serotypes recently reported include the following. A multidrug-resistant invasive serotype 8 has emerged in Spain that is resistant to erythromycin, clindamycin, tetracycline, and quinolones, likely originating from the multidrug-resistant Sweden 15A-ST63 clone.²⁴ Multidrug-resistant putative serotype 6E isolates belonging to clonal complex 90 have been described from 11 Asian countries.^{38,39} A high prevalence of genotype 6E (putative serotype 6E) has been reported among noninvasive/colonization isolates of *Streptococcus pneumoniae* in northern Japan.²⁹⁴ Serotype 11E has been described and differentiated from serotype 11A strains.⁸⁷

PATHOGENESIS

To cause disease, pneumococci, like other extracellular bacterial pathogens, must adhere to mammalian cells, replicate in situ, escape phagocytosis, and damage tissue by causing inflammation or producing substances that directly damage cells and, in some cases, invade the bloodstream.³⁹⁹ The vast array of virulence mechanisms available to pneumococci are countered by numerous host defense mechanisms, although some host responses facilitate infection. Even though colonization with a pneumococcal strain can progress to disease, it usually does not occur, and the development of anticapsular type-specific antibodies occurs within 30 days in older children and adults.^{210,211,401,402} If organisms find their way into the eustachian tubes, sinuses, or bronchi, clearance mechanisms—chiefly, ciliary action—lead to their rapid removal. After the development of humoral immunity, colonization with a strain may persist for 1 to 12 months, during which time disease may occur in contiguous sites, but the host is protected from invasive disease by

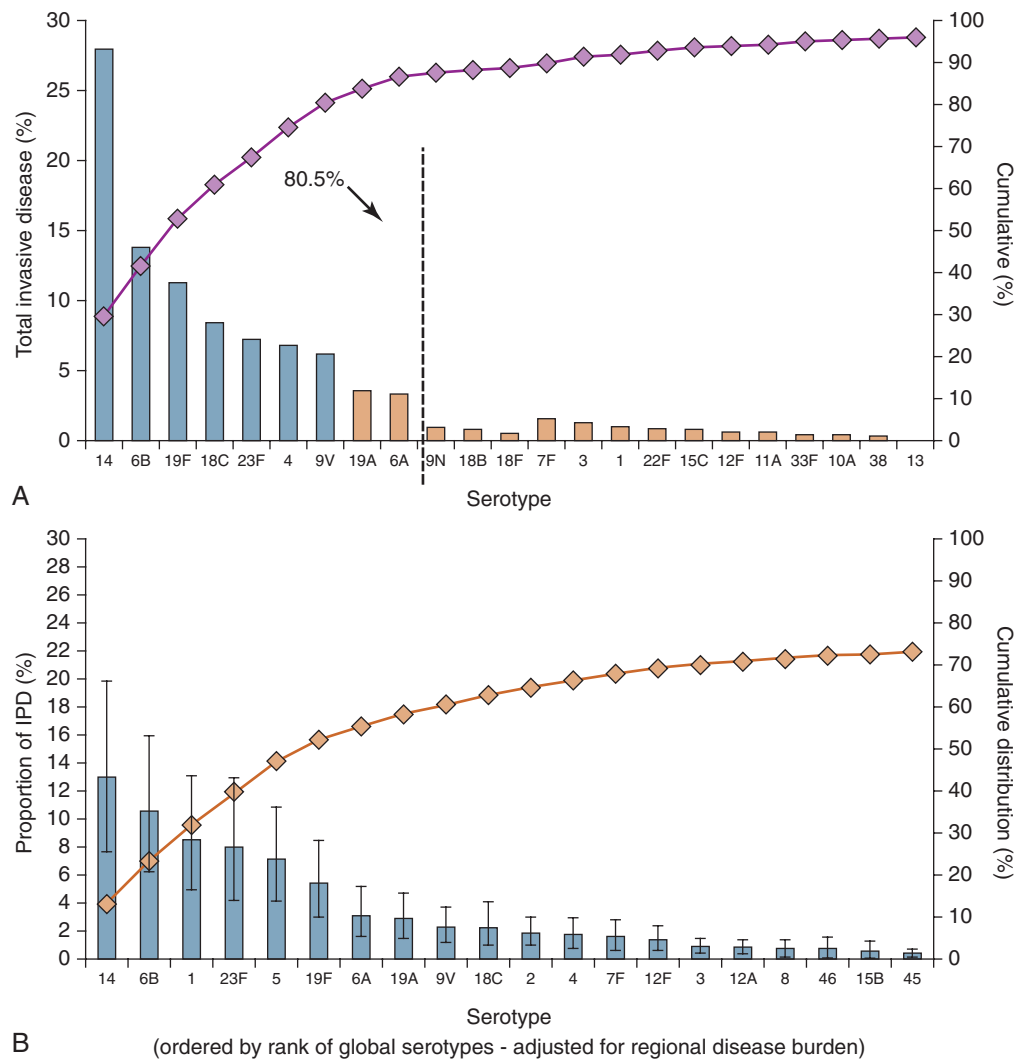

FIG. 85.9 (A) Pneumococcal serotypes causing invasive disease in North American young children prior to PCV7. (B) Proportion of invasive pneumococcal disease (IPD) in young children due to the most common serotypes globally. Error bars indicate 95% confidence interval; cumulative line indicates proportion of IPD due to the 21 serotypes detailed. (A, From Hausdorff WP, Bryant J, Kloek C, et al. The contribution of specific pneumococcal serogroups to different disease manifestations: implications for conjugate vaccine formulation and use, part II. *Clin Infect Dis.* 2000;30:122–40. B, From Johnson HL, Deloria-Knoll M, Levine OS, et al. Systematic evaluation of serotypes causing invasive pneumococcal disease among children under five: the pneumococcal global serotype project. *PLoS Med.* 2010;7:e1000348.)

circulating type-specific anticapsular IgG. Loss of colonization with a strain is followed, after a variable colonization-free interval, by colonization with a different serotype. Because 94 antigenically distinct serotypes exist, this cycle of colonization accompanied by the development of humoral immunity occurs many times.

Progression of colonization to disease usually requires the combination of two events: first, acquisition of a serotype to which the host is not immune; and, second, a concurrent respiratory viral infection, chronic damage to respiratory epithelium (e.g., smoking or exposure to smoke or occupational exposure), allergy, or other conditions that result in the development of disease rather than just colonization.³⁹⁹ Many of these concurrent conditions initiate cytokine activation of the respiratory epithelium, which facilitates increased adhesion of pneumococci to respiratory epithelial cells and invasion of these cells.³⁴¹ Mechanisms by which cytokine activation facilitate pneumococcal adhesion include expression of platelet-activating factor and polymeric immunoglobulin receptor (pIgR). This combination of factors leads to a higher density of colonizing organisms and enables pneumococci to cause infection—including pneumonia, acute exacerbations of chronic bronchitis, sinusitis, otitis media, and mastoiditis—in contiguous respiratory tract sites. Adherence of *S. pneumoniae* to host cells involves

an array of surface adhesin molecules, such as CbpA, PspA, PspC, Hyl, Ply, PsaA, and both neuraminidases (see section on [virulence factors](#) to follow). These proteins are involved in interactions with the host complement system (PspA), degradation of hyaluronan of the extracellular matrix (Hyl), lysis of cholesterol-containing membranes (pneumolysin), and binding of metals (divalent cations) such as Mn^{2+} or Zn^{2+} (PsaA), followed by their transport inside the cytoplasm of pneumococci. Additionally, transepithelial and transendothelial transport of organisms into the bloodstream results in bacteremia; subsequent transport across other epithelial cells leads to infection of noncontiguous sites such as the leptomeninges, peritoneum, and joint spaces. Such infection occurs in nonimmune hosts by virtue of the fact that pneumococci are able to escape ingestion and killing by host phagocytic cells in the absence of type-specific antibody because the capsule inhibits phagocytosis. *S. pneumoniae* produces few toxins and largely causes disease by its capacity to replicate in host tissues and generate an intense inflammatory response. Cell wall teichoic acid and peptidoglycan stimulate the production of cytokines (interleukin-1 [IL-1], IL-6, IL-8, and tumor necrosis factor [TNF]) and activate complement by the alternative pathway. The polysaccharide capsule also activates the alternative complement pathway in vitro. Such activation is associated with the release of C5a, a potent

Site-specific disease potential of individual *Streptococcus pneumoniae* serotypes in pediatric invasive disease, acute otitis media, and acute conjunctivitis. *Pediatr Infect Dis J.* 2006;25:602-7.)

attractant for polymorphonuclear leukocytes (PMNs). The classic complement pathway also is activated and an intense inflammatory response fueled by vigorous activation of both the alternative and classical complement pathways accompanies pneumococcal infection of an immunologically naïve host.³⁹⁹ The disease process is largely a result of this inflammation, and its severity is in direct proportion to its intensity. Pneumolysin also is associated with the severity of disease: injection of pneumolysin into rat lung causes all the histologic findings of pneumonia, whereas immunization of mice with pneumolysin before infection or challenge with pneumolysin-deficient pneumococci is associated with a significant reduction in virulence.^{41,166} Mitchell and Mitchell reported that some nonmeningitis strains of serotype 1 have a mutant nonhemolytic pneumolysin.³⁸⁴ As discussed in the virulence section, numerous other factors contribute to the ability of pneumococcal strains to cause disease and regulate severity.

A 2006 study evaluated the association of serotype with pneumococcal disease among 189 isolates from blood or cerebrospinal fluid (CSF), 3200 isolates from middle ear fluid, and 348 isolates from the conjunctiva of children aged younger than 36 months with pneumococcal infection. A positive association with invasive pneumococcal disease was demonstrated for serotypes 1, 5, and 12F; with AOM for serotypes 1, 3, 5, 12F, 19A, and 19F; and with acute conjunctivitis for nontypeable *S. pneumoniae*.⁵⁰⁶ Although pneumococci most commonly cause bacteremia, otitis media, pneumonia, and meningitis, they can produce disease in virtually any organ. Before the advent of immunotherapy and chemotherapy, such “unusual” infections were relatively common. Today, they are less so. Survival of a patient with a pneumococcal disease depends on numerous variables, including the site of infection, the underlying disease, and the patient’s age. Before the advent of chemotherapy, pneumococcal meningitis was almost universally fatal, whereas pneumococcal pneumonia killed approximately 25% of hospitalized patients. Austrian and Gold in 1964 dramatically illustrated the role of age and underlying disease when evaluating the outcome of bacteremic pneumococcal pneumonia.³³ The aged and infirm were likely to die despite receiving immediate and appropriate therapy with penicillin. Today, healthy children living in high-income countries rarely die of pneumococcal disease; thus, the concern is more related to the development of permanent sequelae. Pneumococci do not usually cause necrosis in pulmonary tissue, and survivors rapidly regain normal pulmonary function.²⁷⁷ Many children recovering from pneumococcal meningitis are found to have neurologic sequelae. Some investigators suggest that the first attack of pneumococcal otitis media in some way predisposes the individual to subsequent attacks of otitis media.²⁵² Before the availability of antimicrobial agents, recovery of a patient with pneumococcal pneumonia depended on the development of type-specific antibody. Although serum and white blood cells (WBCs) from nonimmune children kill pneumococci, probably by activation of the alternative complement pathway, they do so slowly. The importance of this pathway is illustrated best by the inability of children with sickle-cell disease to handle pneumococcal infection.^{139,284,433} These children and others with asplenia may die rapidly despite the administration of prompt, vigorous therapy.^{286,304,499}

MICROBIOLOGY

Structure

Pneumococcal cells are surrounded by a trilamellar, lipopolysaccharide, cytoplasmic membrane that has two electron-dense bands, each 25 Å to 30 Å wide. A cell wall surrounding the plasma membrane has two bands—an inner 30- to 40-Å-wide band and an outer 60- to 80-Å-wide band. Numerous bridges connect the cell wall and the plasma membrane. The polysaccharide capsule covers the cell wall in encapsulated strains and is seen as a wider, less structured band.⁵⁵¹ A schematic representation of the major structural components and selected cell wall components is shown in Fig. 85.11.

Cell Wall Structure

The predominant structural components of the pneumococcal cell wall are peptidoglycan, teichoic acid (TA), lipoteichoic acid (LTA), and several choline-bound proteins. Choline is a lipid that is an essential growth factor for *S. pneumoniae*.

FIG. 85.11 Schematic three-dimensional representation of the major structural components of the cell membrane, cell wall, and capsule of *Streptococcus pneumoniae*. The locations of selected major virulence factors of the organism are shown as well. Chains of lipoteichoic acid are attached to cell membrane glycolipid, whereas surface proteins, such as PspA and CbpA, are in turn attached to the lipoteichoic acid chains via phosphocholine links. PsaA is found on the outer surface of the cell membrane. (Copyright Michael R. Jacobs.)

Peptidoglycan

Peptidoglycan, which accounts for approximately half of the cell wall mass, is a cell wall polymer linked by stem peptides to form a complex, three-dimensional structure.⁵⁰² Stem peptides are formed when trans-peptidases (also known as *penicillin-binding proteins* [PBPs]) link pentapeptide chains into linear stem peptides in penicillin-susceptible strains. However, in non-penicillin-susceptible strains, branched and other variant stem peptides are produced.

Lipoteichoic Acid

LTA also is known as *pneumococcal Forssman (F) antigen*. The LTA of pneumococci possesses identical repeat and chain structures linked to a cell membrane glycolipid that anchors LTA to the cell.^{172,173} Phosphocholine is attached to saccharide residues. PspA and other proteins (discussed later) also are attached to choline residues on LTA.

Teichoic Acid

TA, also known as *pneumococcal C polysaccharide*, has a chain structure similar to that of LTA, except that the saccharide differs. TA chains are attached to the cell wall peptidoglycan. Some phosphocholine residues of both LTA and TA are expressed on the cell wall surface, where they are thought to serve three functions: (1) activation of the pneumococcal autolysin (LytA) enzyme, which is responsible for the autolysis of pneumococci; (2) binding of the choline-binding domain of LytA to choline on TA, which may regulate the activity of LytA; and (3) a function associated with transformability (choline-deficient cells lack transformability).⁵¹⁰

Surface Proteins

Pneumococci have several surface proteins, the five most important being *pneumococcal surface protein A* (PspA), *pneumococcal surface adhesin A* (PsaA), *choline-binding protein A* (CbpA), *hyaluronate lyase* (Hyl), and *pilin protein* (RrgB).

PspA is a cell wall protein with a molecular size of 67 kd to 99 kd that is bound to TA and LTA by phosphocholine links.²⁷⁸ This protein extends through the cell wall and capsule to the surface of the organism.⁶¹³ PspA exists in various antigenic forms, and epitopes within one PspA molecule can recombine into different types.⁷⁷ However, PspA variants usually are sufficiently cross-reactive that immunization with one PspA serotype elicits immunity to other PspA serotypes.

PsaA is a 37-kd surface protein thought to be anchored to the cell membrane and associated with magnesium and zinc transport.¹⁴⁰ It

appears to be a lipoprotein and is common to virtually all *S. pneumoniae* isolates.⁴⁵⁷ Considerable variation in the amino acid sequences of PsaA from different strains has been detected.⁴³¹ The relationship of this protein to other cell wall components has not been determined.⁵⁴¹

CbpA is a protein similar to PspA and has a mass of 75 kD. It is an adhesin involved in the adherence of pneumococci to cytokine-activated human cells.⁴⁷⁶ Several other choline-binding proteins also have been identified.

Hyl is a hyaluronidase that results in breakdown of the hyaluronan and chondroitin sulfate present in the extracellular matrix of human tissues.⁴⁷⁶

Pilin protein (RrgB) is present on the surface of virulent pneumococci in the form of a pilus shaft, which is a long, thin proteinaceous filament extending from the cell wall that aids bacterial colonization in the nasopharynx through epithelial cell binding.⁴³⁰ It has a large adhesive pilin at the tip, a polymeric shaft, and a smaller cell wall anchor, and is comprised of four immunoglobulin-like domains. Isopeptide bond formation in the N-terminal domains, which provides the covalent linkage to the next pilin subunit in the shaft, appears to take place only upon assembly of the pili.

Capsule

The capsule of pneumococci consists of polysaccharides that vary in the make-up of monosaccharides, the sequence of monosaccharides in polysaccharides, the linkage of monosaccharides to each other, and the presence of nonsaccharide components.¹⁶⁷ Currently, 94 serotypes consisting of 25 individual serotypes and 69 serotypes grouped into 21 serogroups are known (see the upcoming section, **microbiology**, and **Table 85.2**). Each serotype has a specific capsular structure, and serotypes within a serogroup often have the same oligosaccharide sequences linked differently. The capsular structure of many serotypes has been determined.³⁶⁹

Several epidemic clones have different serotypes, and extensive genetic changes involving the replacement of entire cassettes of genes related to capsule production are required for capsular switching to take place.⁶

Changes in serotype distribution are the result of both serotype replacement and capsular switching. The role of capsular switching and the extent of vaccine-induced selective pressures on this are not clear. Analysis of serotype and multilocus sequence typing data and whole-genome sequence data for a subset of 426 pneumococci dated from 1937 through 2007 showed that 36 independent capsular switch events had occurred during this time period.⁶⁰⁷ Two events took place no later than 1960, and the imported DNA included the capsular locus and the nearby penicillin-binding protein genes *pbp2x* and *pbp1a*. Capsular switching has therefore been a regular occurrence among pneumococcal populations throughout the past 7 decades. Recombination of large DNA fragments (>30 kb), sometimes including the capsular locus and penicillin-binding protein genes, predated both vaccine introduction and widespread antibiotic use and has likely been an intrinsic feature throughout the history of pneumococcal evolution. These recombination events, including the capsular locus and penicillin-binding protein genes, help explain the evolution of penicillin resistance in pneumococci.

Genome

The complete pneumococcal genome has been mapped. The genome has been estimated to be 2.0 to 2.1 megabases in size, approximately half that of *Escherichia coli*.^{44,143} The locations of more than 100 genes, including 20 tRNA synthetase and 20 ribosomal protein genes, have been mapped. Genes involved in cell wall synthesis also have been identified. *S. pneumoniae* is a naturally transformable bacterium, which means that it is able to take up single-stranded DNA from its environment and incorporate this exogenous DNA into its genome. This process is known as *transformational recombination*.^{393,523} Recombination is a powerful means of genome evolution and provides a great degree of genome flexibility to this organism. Transformation occurs only at high cell densities (10^5 – 10^8 colony-forming units/mL), and a peptide pheromone quorum-sensing signal called *activator* or *competence factor* is required.⁴⁵³ This factor also is called *competence-stimulating peptide*.⁵²⁶ The genes associated with capsule synthesis have been characterized for several serotypes as well. The complete nucleotide

sequence of many of these genes of several *S. pneumoniae* serotypes has been determined.^{27,185,390,586}

While next-generation sequencing has revolutionized bacterial genomics, major barriers still exist to its implementation for routine microbiological use in public health and clinical microbiology laboratories.⁴⁸¹ These limitations include the inherent complexity and high frequency of data analyses on very large sets of DNA sequence data, the ability to ensure data integrity, the need for quick and accurate results, and the lack of a user-friendly interface.

Virulence Factors

Animal models of pneumococcal infection have provided considerable insight into the pathogenesis of disease and the association of virulence factors with disease. However, the pneumococcus is primarily a human pathogen, and the host defenses of animal models can vary significantly from those in humans. For example, pneumococci adhere to human but not to rabbit pIgR.^{50,619} Additionally, virulence in mice varies considerably with the strain of pneumococcus: pneumococci belonging to serogroups 6, 14, 19, and 23 rarely are virulent in mice, whereas serotypes 1, 2, and 3 usually are virulent.^{76,619} Virulence also may vary according to the mouse strain.^{1,31,35,319,462,548}

Some serotypes can be virulent to one species of animal but not to others. An example is serotype 19F, which rarely is virulent in mice³⁵ but is highly virulent in guinea pigs.³¹ In addition, penicillin resistance appears to be linked to decreased virulence by virtue of the fact that virulence of isogenic mutants of a virulent, penicillin-susceptible strain was reduced significantly when transformed into a penicillin-resistant strain with an abnormal *pbp2x* gene.⁴⁶² Therefore, many animal models of pneumococcal virulence may not be representative of virulence in humans or representative of all pneumococcal serotypes or antimicrobial-resistant strains.

Although the polysaccharide capsule has been recognized as the major determinant of virulence, relatively little is known about the molecular basis of the pathogenesis of pneumococcal disease. A library of 1786 pneumococcal mutants created by insertion-duplication mutagenesis was analyzed for their ability to survive and replicate in murine models of pneumonia and bacteremia.³²⁸ A total of 186 mutant strains exhibited attenuated virulence; 56 of these strains were genetically characterized, and genomic DNA inserts were sequenced and subjected to database searches. Most of the insertions were in probable operons, but no pathogenicity islands were found. Forty-two novel virulence loci were identified. Five strains showed mutations in genes involved in gene regulation, cation transport, or stress tolerance; the virulence of these strains was shown to be highly attenuated in a murine respiratory tract infection model. Additional experiments also suggest that induction of competence for genetic transformation has a role in virulence.³²⁸ This approach has revealed several previously unrecognized genes required for virulence.

A similar genomic approach was used to look for genes coding for surface-localized proteins that could be targets for protective humoral immunity. By exploiting the whole genome sequence of *S. pneumoniae*, researchers found 130 open-reading frames encoding proteins with secretion motifs or similarity to predicted virulence factors.⁵⁹¹ Mice were immunized with 108 of these proteins; 6 conferred protection against disseminated pneumococcal infection. Each of the six protective antigens showed broad strain distribution and immunogenicity in human infections. Some of these proteins have been identified as LytB, LytC, and a cell wall-anchored serine protease. Another genomic-based study used a genomic expression library of *S. pneumoniae* screened with convalescent-phase serum for immunoreactive proteins.⁶²³ Six known and 17 unknown pneumococcal proteins were detected. Five of the known proteins, including PspA and SpsA (CbpA), were surface-located virulence factors; eight of the unknown proteins were putative membrane proteins. Use of these genomic approaches for the identification of novel microbial targets to elicit a protective immune response has been validated. These new antigens may play roles in the development of improved vaccines against *S. pneumoniae*.

Capsule

The capsule is the major determinant of virulence in pneumococci. It prevents phagocytosis by PMNs and macrophages, thereby allowing

unrestricted extracellular multiplication of the organism. Because the pneumococcus has 94 antigenically distinct serotypes, production of anticapsular antibody in response to one serotype provides protection against only that serotype or serogroup, whereas nonencapsulated strains are considerably less virulent.³⁹⁹ The importance of the capsule as a virulence factor is emphasized by the fact that protection from pneumococcal infection can be achieved by capsular-specific antibodies. Despite the large number of additional virulence factors (described in the following), the capsule remains the single most important determinant of virulence in avoiding host defenses after the epithelial barriers have been breached. Other virulence factors are important in breaching host defenses, such as epithelial barriers.

Neuraminidases

Neuraminidases are enzymes that cleave terminal sialic acid residues from glycolipids, glycoproteins, and oligosaccharides on eukaryotic cell surfaces; such cleavage may unmask cell surface receptors for pneumococcal adhesins.⁴³¹ The neuraminidase NanA has been implicated in the ability of *S. pneumoniae* to colonize and persist in the nasopharynx and middle ear.⁵⁵² A second neuraminidase, NanB, has much weaker activity than NanA does but exhibits optimal activity at pH 5, whereas NanA is most active at pH 7.⁴³¹

Pneumolysin

Pneumolysin, also known as hemolytic pneumolysin (PLYh), is a 53-kD cytoplasmic protein produced by all pneumococci. It is essential for the initial binding to membrane cholesterol and the interaction leading to subsequent membrane damage.³⁶

Functions of pneumolysin include the following:

1. Pore formation in host epithelial cell membranes: Pneumolysin binds to cholesterol in host epithelial cell membranes, where oligomers of pneumolysin molecules assemble to form 35- to 45-nm pores in the cell membrane, which results in lysis of the targeted cell. Pneumolysin is, therefore, cytotoxic to epithelial cells. It also slows ciliary beating of bronchial epithelial cells and disrupts the tight junctions between epithelial cells. In addition, pneumolysin disrupts alveolar epithelial cells and the alveolar-capillary boundary, thereby facilitating entry of pneumococci into the bloodstream and through the blood-brain barrier.^{195,624}
2. Effects on phagocytic and immune cell function: Pneumolysin attracts neutrophils in the early phases of disease and lymphocytes at a later stage.
3. Direct activation of the complement system: Expression of pneumolysin by pneumococci reduces serum complement levels and serum opsonic activity.¹⁰
4. Promotion of nitric oxide (NO) production by macrophages: NO is produced by an inducible NO synthase during inflammation as an essential element of antimicrobial defense, but it also can contribute to host-induced tissue damage.⁷⁴

Some serotypes, such as 1 and 8, express an ahemolytic pneumolysin, PLYA, in place of PLYh.²⁹⁹ These serotypes are associated with low colonization rates but high rates of invasive disease. Mice colonized with PLYa-expressing strains had significantly higher colonization densities than those colonized with hemolytic pneumolysin (PLYh)-expressing strains, irrespective of capsular background. PLYa-expressing strains induced diminished innate (dendritic cell cytokines, costimulatory receptor, and apoptotic) and adaptive (CD4⁺ T-cell proliferative and memory interleukin 17A) responses. Replacement of PLYh with PLYa can therefore change colonization and virulence properties of serotypes.

Surface-Located Choline-Binding Proteins

The virulence of members of the choline-binding protein (Cbp) family and two cell wall hydrolases, LytB and LytC, has been characterized.²⁰⁵ Cbp-, LytB-, and LytC-deficient mutants show significantly reduced colonization of the nasopharynx. The following proteins of the Cbp family and their virulence mechanisms have been described:

1. *PspA* is a serologically variable protein that has undergone extensive recombination.²⁴⁷ It is thought to exert its virulence function in systemic infection by interfering with deposition of the complement

component C3b onto pneumococci or by blocking recruitment of the alternative pathway, thereby reducing the effectiveness of complement receptor-mediated pathways of clearance.⁵⁵⁶ *PspA* has been shown to bind to lactoferrin, an iron-sequestering glycoprotein found in mucosal secretions, when the level of free extracellular iron is not sufficient for the growth of pneumococci. This binding is thought to overcome the iron limitation at mucosal surfaces and might represent a potential virulence mechanism for colonization of mucosal surfaces.²²⁶

2. CbpA, or *SpA*, is a surface protein adhesin that acts as a bridging element between pneumococci and host-cell glycoconjugates on cytokine-activated host cells.²²⁷ This process is thought to be associated with change from nasopharyngeal colonization to invasion of epithelial and endothelial cells.⁴⁷⁶ One mechanism by which this process occurs, wherein CbpA binds to the pIgR of human epithelial cells, has been described.⁵²⁰ The pneumococcus co-opts the IgA transcytosis machinery and gains entry into and across airway epithelial cells. This process is a novel example of a pathogen co-opting the transcytosis machinery to promote translocation across a mucosal barrier.²⁸⁸
3. *PsaA* is a surface protein that also is associated with virulence via adhesion to epithelial cells.
4. Pneumococcal histidine-containing protein A (PhpA) is a 20-kD protein with putative proteolytic activity against the human complement component C3. PhpA is a potential candidate for use as a vaccine against systemic pneumococcal disease and otitis media.⁶¹⁹
5. The pneumococcal histidine triad (Pht) proteins PhtA, PhtB, PhtD, and PhtE constitute a novel family of homologous surface proteins associated with virulence; they are also potential vaccine candidates.⁹ Although antibodies targeting PhtA, PhtB, or PhtD are protective, the function of these proteins remains unknown. The number of histidine and tyrosine residues in these proteins suggests that they may be involved in metal or nucleoside binding.
6. Hic, a member of the pneumococcal surface protein C (PspC) family, is associated with resistance of serotype 3 strains to opsonophagocytosis due to recruitment of the complement inhibitor factor H by Hic.³¹⁴ Hic also interacts with vitronectin, a fluid-phase regulator involved in hemostasis, angiogenesis, the terminal complement cascade and a component of the extracellular matrix. This interaction of Hic with vitronectin and factor H may contribute to colonization and invasive disease caused by serotype 3 pneumococci.

Phase Variation

Phase variation in the colonial opacity of *S. pneumoniae* has been implicated as a factor in bacterial adherence, colonization, and invasion.⁵⁹⁰ On clear media, colonies can appear as opaque or translucent when viewed under magnification with oblique transmitted light. All strains of *S. pneumoniae* are thought to be capable of phase variation. Opaque colonies are less likely to autolyze, contain less TA but more *PspA* in their cell walls, and colonize the nasopharynx poorly in animal models but are more virulent when inoculated into sterile sites. Conversely, translucent colonies are more likely to autolyze, contain more TA but less *PspA* in their cell walls, and colonize the nasopharynx well but are less virulent when inoculated into sterile sites. Translucent colonies become umbilicated as a result of autolysis, whereas opaque colonies remain dome shaped.

Phosphorylcholine Esterase

This enzyme has activity that removes phosphorylcholine residues from cell wall TA and LTA.⁵⁷⁴

Inactivation of the gene encoding for the enzyme in pneumococcal strains caused a change in colony morphology from translucent (colonizing) to opaque (virulent) and a striking increase in virulence in the intraperitoneal mouse model. Phosphorylcholine esterase therefore appears to be a regulatory element involved in the interaction of *S. pneumoniae* with its host.

Pneumococcal Autolysin

Pneumococcal autolysin (LytA) is a 36-kD cell wall protein attached to choline residues on TA and LTA. It is associated with unlinking of cell wall glycan from stem peptides during cell remodeling and division.

Autolysin initially was considered to be a significant virulence factor, but more recent work has shown that it plays only a minor role and that immunization with autolysin does not provide protection.⁴³¹

Cell Wall Stem Peptides

The peptidoglycan of gram-positive bacteria triggers the release of cytokines from peripheral blood mononuclear cells.³⁶⁴ However, 100 to 1000 times more gram-positive peptidoglycan than gram-negative lipopolysaccharide endotoxin is required to release the same amount of cytokine. Simple stem peptides were 10-fold less active than was undigested peptidoglycan in stimulating TNF. In contrast, complex branched peptides such as tripeptides were at least 100-fold more potent than was the native material. These complex branched peptides represented 2% or less of the total material, but their activity in stimulating TNF was almost equal to that of endotoxin.

Iron Transport

The availability of iron is a major requirement for the growth and survival of many organisms, including *S. pneumoniae*. Two *S. pneumoniae* genetic loci, *pit1* and *pit2*, which encode homologues of ABC iron transporters, are required for uptake of iron by this organism.⁸⁰ Virulence in mouse models of pulmonary and systemic infection is attenuated moderately with a *pit2*-disrupted strain and attenuated strongly with a *pit1/pit2*-disrupted strain.

IgA Protease

IgA proteases belong to a family of proteins used by a diverse group of bacteria, including *S. pneumoniae*, for colonization and invasion. IgA1 protease allows bacteria to cleave human IgA1 in the hinge region. The exact role of these enzymes in bacterial pathogenesis is not understood completely, but they are important in bacterial colonization of mucosal membranes in the presence of secretory IgA antibodies by causing local IgA deficiency.³⁰⁰ The IgA protease genes of *S. pneumoniae* and *Streptococcus mitis* show extensive polymorphism, which results in enzymes with considerable antigenic diversity.⁴⁴⁷

Phosphoglucosyltransferase

Phosphoglucosyltransferase is an enzyme that is necessary in one of the early steps in capsular polysaccharide synthesis. *S. pneumoniae* mutants lacking this enzyme do not produce a capsule and are avirulent in immunocompetent but not in immunosuppressed mice.²²⁸ Other metabolic pathways also are thought to be affected by this enzyme.

Free Oxygen Radicals

Release of free oxygen radicals has been implicated in the pathogenesis of otitis media by *S. pneumoniae*. Antibiotic killing of bacteria leads to the release of further free oxygen radicals, which results in tissue damage despite the administration of appropriate antibiotic therapy.⁵³⁹ Reactive oxygen intermediates also mediate brain injury in bacterial meningitis.^{30,352}

Nicotinamide Adenine Dinucleotide Plus Hydrogen Oxidase

Reduced nicotinamide adenine dinucleotide plus hydrogen (NADH) oxidase has been shown to be a virulence factor necessary for *S. pneumoniae* infection. The basis of NADH oxidase as a virulence factor is the conversion of O₂ to H₂O. If O₂ is not reduced fully, it can form superoxide anion (O₂⁻) and hydrogen peroxide (H₂O₂), both of which can be toxic to cells.⁶¹⁴

Pyruvate Oxidase

Pyruvate oxidase decarboxylates pyruvate to acetyl phosphate plus H₂O₂ and CO₂ and appears to be associated with regulation of the multiple adhesive properties of pneumococci.⁵²² A pneumococcal mutant lacking the gene encoding pyruvate kinase showed a greater than 70% loss of the ability to attach to all cell types.

Plasminogen Binding and Penetration of the Basement Membrane

Binding of plasminogen plus penetration of the basement membrane is thought to be an essential step in the pathogenesis of bacterial meningitis.¹⁴⁹ Most strains adhere to reconstituted basement membrane,

as well as to its purified laminin and collagen IV components, and to bound plasminogen. Penetration of the basement membrane was achieved within 3 to 4 hours in the presence of plasminogen; without plasminogen, no penetration occurred.

Hyaluronidase

Virtually all pneumococcal strains produce the enzyme hyaluronidase, a 107-kD protein. Models used to simulate human meningitis generally involve the direct intracerebral route of infection. However, intranasal inoculation would provide a more realistic model; this was achieved by intranasal administration of *S. pneumoniae* with hyaluronidase. This model induced meningitis in 50% of inoculated mice; meningitis did not develop in any of the mice inoculated without hyaluronidase. Hyaluronidase was found to facilitate pneumococcal invasion of the bloodstream after colonization of the upper respiratory tract. This murine model mimics important features of human disease, which allows the model to be used to study issues related to the pathogenesis and treatment of pneumococcal meningitis.⁶²²

Peptidoglycan N-Acetylglucosamine Deacetylase A

The glucosamine and muramic acid residues of the pneumococcal cell wall traditionally are regarded as being N-acetylated. However, more than 80% of the glucosamine and 10% of the muramic acid residues have been shown to be deacetylated, thereby explaining the resistance of peptidoglycan to the hydrolytic action of lysozyme, a muramidase that cleaves the glycan backbone.⁵⁷³ A gene that encodes for peptidoglycan N-acetylglucosamine deacetylase A has been identified. This gene may contribute to pneumococcal virulence by providing protection against host lysozyme, which is known to accumulate in high concentrations at sites of infection.

Phages

Whereas transformation is recognized as occurring in pneumococci, another mechanism of DNA transfer in pneumococci is transduction of DNA carried by bacteriophages (lysogeny). A high proportion (76% of 791 isolates) of clinical isolates of pneumococci were found to carry multiple copies of *lytA*, thus indicating the widespread occurrence of lysogeny in pneumococci.⁴⁵⁴ The *lytA* hybridization pattern of a strain has been found to be stable during extensive serial culturing; it is specific for the clonal type of the strain and can be used as a molecular epidemiologic marker. In addition, phage DNA integrated into the pneumococcal genome acts as an integrase to facilitate the introduction of foreign genes into the pneumococcal chromosome.¹⁹⁶

Tolerance

The ability of *S. pneumoniae* to escape lysis and killing by vancomycin and penicillin, a property termed *tolerance*, has been described.²⁴² Among 116 clinical isolates of pneumococci, 3% and 8% were tolerant to vancomycin and penicillin, respectively. Tolerance may contribute to treatment failure, particularly in meningitis, in which bactericidal activity is critical for eradication. A vancomycin- and cephalosporin-tolerant strain of *S. pneumoniae*, the Tupelo strain, has been isolated from the CSF of a patient in whom recrudescence of meningitis developed despite treatment with vancomycin and a third-generation cephalosporin.⁵⁷³ The defect leading to tolerance in this strain involves the control pathway for triggering of autolysis via a mutated *CiaH* histidine kinase.³⁹⁴ A frameshift mutation in the *lytA* gene encoding the main pneumococcal autolysin was associated with vancomycin tolerance in another strain.³⁹⁴

Respiratory Viral Infections

The role of respiratory viral infection in predisposing the host to secondary bacterial infection—including pneumonia, empyema, and lung abscess—is well recognized.³⁴¹ The lungs of immunocompetent mice infected with influenza A virus on day 1 and *S. pneumoniae* on day 8 demonstrate greater *S. pneumoniae* colony counts, more extensive neutrophil infiltration, and higher lung levels of IL-1 β and TNF- α after exposure to *S. pneumoniae* than do the lungs of control mice not preinfected with influenza virus.³⁴¹ Influenza A virus facilitates *S. pneumoniae* transmission and disease, with secondary bacterial pneumonia representing an important cause of excess mortality during both

influenza epidemics and pandemics.^{11,138} This lethal synergism between influenza virus and *S. pneumoniae* was first suggested by studies performed on samples collected during autopsy from victims of the 1918 influenza pandemic and was confirmed by data collected during the 2009 A/H1N1v influenza pandemic.

Glycerophosphodiester Phosphodiesterase (GlpQ)

This enzyme is produced by the lung epithelium and metabolizes glycerophosphorylcholine to produce free choline, which is transformed into phosphorylcholine, which is present on the surfaces of many respiratory pathogens.¹⁰⁰ *S. pneumoniae* has two orthologs of glpQ genes: glpQ is widespread in pneumococci, whereas glpQ2, which is similar to glpQ in *Haemophilus influenzae* and *Mycoplasma pneumoniae*, is present only in *S. pneumoniae* serotype 3, 6B, 19A, and 19F strains. The presence of glpQ2 in serotype 19A enhances surface phosphorylcholine expression and contributes to the severity of pneumonia by promoting adherence and host cell cytotoxicity.

Regulatory System 11

This is a two-component regulatory system, TCS11, consisting of the sensor kinase, hk11, and its cognate response regulator, rr11. Regulatory system 11 is associated with biofilm formation and is postulated to be associated with airway colonization.¹⁰⁴ This regulatory system is upregulated by exposure to cigarette smoke, which would thereby enhance colonization.

ftsY

ftsY is a gene coding for a central component of the signal recognition particle (SRP) pathway that is responsible for delivering membrane and secretory proteins to their proper cellular destination.⁴⁷³ Deletion of this pathway is lethal to many bacterial species but is tolerated in streptococci, although these strains have decreased virulence. Such strains are therefore attractive live vaccine candidates, as they colonize but do not cause invasive disease. In a mouse model, a live vaccine candidate with deletion of *ftsY* induced serotype-independent protection against otitis media, sinusitis, pneumonia, and invasive pneumococcal disease. This protection was maintained in animals coinfecting with influenza virus but was lost if mice were depleted of CD4⁺ T cells.

spxB Mutations

Large-colony variants of serotype 1 strains are associated with higher numbers of viable faster-growing bacteria that produce no or little hydrogen peroxide.⁵³³ These variants contain mutations in the *spxB* gene and have been shown to be considerably more virulent in mice and less susceptible to early host clearance than wild-type strains after intravenous infection but impaired in colonization. Additionally, *spxB* mutants were less efficiently phagocytosed by macrophages. These *spxB* mutants are hypervirulent in both mice and patients and are resistant to early macrophage-mediated clearance.

Diagnostic Microbiology

S. pneumoniae is a gram-positive coccus that replicates in pairs and chains in liquid medium. The shape of the individual organism is a lanceolate coccus, usually in pairs, with the long axis forming a straight line. Elongated or pointed forms are commonly found.

Isolation

Pneumococci are cultured readily on blood and chocolate agar media, as well as in suitable liquid culture media for isolation from blood. Isolates are facultative anaerobes, and most strains require atmospheric enrichment with 5% to 10% CO₂ for primary isolation³²; occasional strains are strict anaerobes. Strains can be adapted for growth without CO₂ supplementation by repeated subculture. Detection of nasopharyngeal carriage of pneumococci is a problem because of the presence of other flora; the use of antimicrobial-containing media, such as blood agar supplemented with gentamicin (5 µg/mL), has led to improvements in isolation of pneumococci, particularly resistant strains.^{434,451} However, the sensitivity of current in vitro methods is poor in comparison to the sensitivity of mouse inoculation, although not all serotypes are virulent in mice.^{246,312}

Identification

Pneumococci usually are identified readily by standard features such as colonial morphology, alpha-hemolysis, negative catalase reaction, optochin susceptibility, bile solubility, and specific reactions with antisera to capsular polysaccharides.²⁶⁴ *S. pneumoniae* produces an autolytic intracellular enzyme, LytA, that causes the organism to autolyze rapidly when grown on artificial media. Bile salts and optochin accelerate this natural autolytic process by combining with the pneumococcal cell and activating its autolysin. Strains with atypical features—such as rounded rather than flat or concentrically ringed colonies, optochin resistance, or lack of capsules—do occur and can result in misidentification of such strains as viridans streptococci. Atypical strains are more likely to be encountered from normal flora sites and with penicillin-resistant strains. Molecular methods for identification of pneumococci include PCR detection of *ply* and *psaA* genes, multilocus sequence typing, 16S rRNA gene sequencing, and pyrosequencing. The presence of *psaA* is useful in distinguishing between atypical pneumococci and other streptococcal species.²⁶⁴

Strains with optochin zones greater than 14 mm can be identified presumptively as pneumococci, strains with 7- to 14-mm zones require confirmation by bile solubility, and strains with no zone usually are not *S. pneumoniae*. However, incubation in carbon dioxide has been recognized for a long time as decreasing the size of the zone around optochin disks, and incubation in room air generally results in an increase in zone size if the strain is a pneumococcus or a decrease if the strain is a member of the viridans group of streptococci.⁴⁵² Optochin-resistant variants of pneumococci can occur and usually are seen as a subpopulation within the zone of inhibition of an optochin disk, and optochin-resistant mutants can be selected by passage of strains in the presence of optochin.³⁹⁸ Strains with equivocal optochin zones or atypical colonial morphology can be tested for bile solubility either directly by placing a drop of bile salt solution (10% sodium deoxycholate) onto colonies and observing for lysis of the colonies or by suspension of organisms in a bile salt solution with a bile salt-free control. Care must be taken in the tube bile solubility test to avoid obtaining false-positive results, which can be caused by the organism suspension being too light or by organisms being suspended in broth rather than saline.²⁶⁴

Matrix-assisted laser desorption ionization-time of flight mass spectrometry fingerprinting systems are increasingly being used for bacterial identification in the routine diagnostic microbiology laboratory but may not adequately differentiate pneumococci from species within the *Streptococcus mitis* group, which includes *S. pneumoniae*. A comparative analysis of matrix-assisted laser desorption ionization-time of flight spectra of several species from the *S. mitis* group suggests that it is possible to distinguish different species of the *S. mitis* group by close analysis of their mass peak profiles.⁵⁹²

Identification of the capsular polysaccharide serotype or serogroup also is useful in characterizing strains and confirming the identity of problem strains. Such identification is performed by the capsular swelling technique, in which equal volumes of an organism suspension—0.3% methylene blue dye solution and antiserum—are mixed on a glass slide, covered with a coverslip, and read at ×1000 magnification by phase-contrast microscopy. Alternatively, organism suspensions can be dried on slides and antiserum and methylene blue dye solution mixed on a coverslip, which then is placed on the slide. The polysaccharide capsule of the pneumococcal organism binds with type-specific antiserum and organisms can be seen to clump or agglutinate. The resulting change in the refractive index of antibody-coated capsule causes the capsule to appear swollen. Currently, antisera to each serotype or serogroup and factoring antisera to subtype serogroups are available from Statens Serum Institut, Copenhagen, Denmark.²⁴¹ The numbering system for pneumococcal serotypes is shown in Table 85.2.

Currently, 94 serotypes have been identified and are divided into 25 individual serotypes and 21 serogroups in the Danish classification, which now is used universally. Most serotypes have one antigenic determinant, whereas serogroups have one or more antigenic determinants common to the group and one or more determinants unique to each serotype. Serotypes within a serogroup usually are identified by the serogroup number, followed by a letter indicating the serotype to which a strain belongs. Except for serogroups 6 and 9, the letters are F

for the first subtype, followed by A, B, and so on. Each serogroup contains 2 to 6 related types; the 21 serogroups currently include over 67 individual subtypes. Serotype numbers 26 and 30 are not in use. Serotype 2, an extremely uncommon pneumococcal serotype, was detected as the leading pneumococcal serotype (20% of 221 cases) in childhood meningitis in Bangladesh.⁴⁸⁴ These serotype 2 strains had three closely related pulsed field gel electrophoresis types.

Omniserum containing antibodies to all serotypes is available and can be used to confirm the identity of isolates as pneumococci. Because many serotypes or serogroups are included in this reagent, reactions may not always be optimal and usually are stronger in pool or monovalent reagents. Nine antiserum pools classified from A to I, each containing four to seven serotypes or serogroups, also are available and can be used to identify strains in a group of serotypes before individual serotype or serogroup reagents are tested. Other methods of capsular typing can be used—such as latex agglutination, coagglutination, and capillary precipitation—but these methods are not available commercially.

The ability of a polymerase chain reaction (PCR) method to identify the capsular serotype of pneumococci has been developed on the basis of polymorphisms in two genes common to the different capsule loci.³³¹ PCR holds promise as a noncultural method for determining serotype, and multiple methods have been developed. An example is a high throughput nanofluidic real-time PCR-based assay using 29 primer pairs to cover 50 serotypes. This assay is able to differentially quantify 29 pneumococcus groups for 45 test samples in a single run and can be used for large-scale epidemiologic studies.¹³⁶

Detection of Clonality

In addition to phenotypic features, such as serotype and antimicrobial resistance markers, various DNA fingerprint methods for epidemiologic typing of *S. pneumoniae* have been applied. The currently recognized reference method is multilocus sequence typing, in which 450 bp fragments of seven housekeeping loci are determined. The combination of alleles at these seven loci provides a sequence type, and the relatedness between isolates is obtained by constructing a dendrogram from the matrix of pairwise differences between sequence types.^{156,148,363} Other typing methods include ribotyping, BOX fingerprinting with the BOX repetitive sequence of *S. pneumoniae* used as a DNA probe, PCR fingerprinting with a primer homologous to the enterobacterial repetitive intergenic consensus sequence, pulsed-field gel electrophoresis of large DNA fragments digested by restriction enzymes, and detection of polymorphic DNA sequences for a Multiple-Locus Variable-Number Tandem-Repeat Analysis.^{243,374}

Diagnosis of Pneumococcal Disease

Definitive diagnosis of pneumococcal infection is based on recovery of pneumococci from the site of infection or documentation of pneumococcal bacteremia, whereas presumptive diagnosis is based on detection of pneumococcal cellular components, such as capsular polysaccharide, or on species-specific DNA and RNA sequences from the site of infection or from remote sites, such as urine.²⁶⁴ Definitive diagnosis is confounded in many instances by the need for invasive procedures to obtain specimens (e.g., from the middle ear space) and by nasopharyngeal carriage of pneumococci when sputum is cultured. Pneumococci almost invariably are isolated from CSF in pneumococcal meningitis, even in patients receiving oral antibiotics.⁴⁷⁷

However, establishing the diagnosis of pneumococcal pneumonia is more challenging because sputum rarely is available from children and direct lung puncture is performed very infrequently. Detection of pneumococcal bacteremia to confirm the diagnosis of pneumococcal pneumonia or other localized infection is valuable, but it does not occur frequently and the actual prevalence of bacteremic pneumococcal pneumonia in children is not known,⁵⁴⁷ although a study suggests that the prevalence is approximately 17% (11/64).³⁷⁸ Therefore, pediatricians must use other methods to diagnose pneumococcal pneumonia. Signs and symptoms significantly associated with bacteremic pneumococcal pneumonia in children include high temperature ($>38.9^{\circ}\text{C}$ [$>102^{\circ}\text{F}$]), leukocytosis ($>15,000/\text{mm}^3$), and lobar or segmental consolidation.⁵⁴⁷ However, the frequency with which these findings are associated with nonbacteremic pneumococcal pneumonia is not known.

With the widespread deployment of pneumococcal vaccine, occult bacteremia caused by *S. pneumoniae* occurs less commonly. The likelihood that a positive blood culture will be a false-positive result is increased if the WBC count is less than $15,000/\text{mm}^3$, the time for the blood culture to become positive exceeds 24 hours, or the Gram stain result is suggestive of a contaminant.⁴⁹¹

Direct examination of Gram-stained smears of clinically appropriate material remains the fastest diagnostic method and can be augmented if necessary by direct demonstration of capsular swelling of organisms in the presence of anticapsular antisera. The availability of antigen-detection systems that can be used in urine, serum, CSF, and other specimens, such as capsular antigen detection by counterimmunoelectrophoresis and latex agglutination with polyvalent pneumococcal reagent, generally has not improved patient management because of the low sensitivity and specificity of these methods and the fact that they usually are positive only when a Gram stain also is positive. The concentration of pneumococcal capsular antigen in saliva was evaluated by latex agglutination in a study consisting of children with CAP and healthy controls. None of the children with pneumonia in this study had a positive blood culture, and pneumococcal capsular antigen was detected in the saliva of 27% of children with pneumonia versus 17% of controls. More cases (20%) than controls (2%) had a pneumococcal capsular antigen titer of 10 or greater ($P < .01$). Quantitative measurement of pneumococcal capsular antigen in saliva may be valuable in helping to make an etiologic diagnosis in children with pneumonia, but its sensitivity is poor and it is confounded by false-positive results caused by pneumococcal carriage.¹⁷⁵

A rapid (15-minute) immunochromatographic membrane test to detect pneumococcal polysaccharide capsular antigen in urine samples (Binax NOW) has been developed and was evaluated in the diagnosis of bacteremic and nonbacteremic pneumococcal pneumonia. Urine samples were studied in 51 patients with bacteremic and nonbacteremic pneumonia caused by *S. pneumoniae*. The pneumonia was diagnosed by blood culture and pneumococcal polysaccharide capsular antigen was detected by counterimmunoelectrophoresis in urine samples. Pneumococcal antigen was detected in urine by the immunochromatographic membrane test in 41 of 51 patients with pneumococcal pneumonia (80.4%), including 23 of 28 bacteremic cases (82.1%) and 18 of 23 nonbacteremic cases (78.3%). Antigen also was detected in seven of 16 patients with a diagnosis of presumptive pneumococcal pneumonia (43.7%) and in one of the 16 patients with pneumonia but in whom no pathogen was identified. The specificity of the immunochromatographic membrane test was 97.2%, but its sensitivity was only approximately 80%, thus limiting its value.¹⁷⁵ Furthermore, the usefulness of this test is questionable because the antigen was detected in the urine in 30 of 138 (22%) healthy children with nasopharyngeal carriage of *S. pneumoniae* versus only 3 of 71 (4%) noncarriers ($P < .001$).²²⁵ Thus, the test was shown to be often positive in healthy pneumococcal carriers.

One study found that immunochromatographic testing for *S. pneumoniae* in CSF was both 100% sensitive and specific. The simplicity of the test and the longevity of the CSF antigen even after treatment suggest potential utility of this method in identifying *S. pneumoniae* meningitis in resource-poor countries with widespread prehospital antimicrobial use.⁴⁸⁵ Another study showed immunochromatographic testing to be more sensitive than culture in detecting *S. pneumoniae* as the causative agent in thoracic empyema.⁴⁴²

Newer molecular-based methods for establishing the diagnosis of pneumococcal disease include the use of DNA probes to detect pneumolysin, autolysin, and PsaA protein. However, considerable practical problems must be overcome before these methods will be applicable clinically.¹²⁵ Examples include a commercial method involving real-time PCR for simultaneous detection of *N. meningitidis*, *H. influenzae*, and *S. pneumoniae* in patients suspected of having meningitis and septicemia. This method is based on detection of the pneumolysin gene for *S. pneumoniae* and uses a single-tube, 5'-nuclease multiplex PCR assay on samples of CSF, plasma, serum, and whole blood. Amplified products are monitored with sequence-specific, fluorescent dye-labeled probes. The sensitivity of using clinical samples (CSF, serum, plasma, and whole blood) from culture-confirmed cases of *S. pneumoniae*

infection was 91.8%. The multiplex assay also was used to test a large number of culture-negative samples, which resulted in the detection of numerous cases of meningococcal, *H. influenzae*, and pneumococcal disease that had not been detected by culture.⁵³⁶ However, whether these results are true positives or false positives is not known and, in another study, although the sensitivity of PCR amplification of the pneumolysin gene in the serum and CSF of infants and children with culture-proven pneumococcal bacteremia and meningitis was 100%, the specificity was poor, with 17% of healthy controls having positive results.¹²⁵ The prevalence of false-positive reactions was highest (33%) in 2-year-old children, the age group with the highest rate of nasopharyngeal carriage of pneumococci. Therefore, although PCR of serum and CSF is a sensitive test for the detection of *S. pneumoniae* in these sites, its high rate of positivity in healthy controls as a result of nasopharyngeal carriage limits its utility in detecting systemic pneumococcal infection.¹²⁵

Another rapid PCR method involving the use of a set of primers that amplify 273 base pairs of the autolysin gene has been developed to identify *S. pneumoniae*. In addition, three sets of primers were designed to amplify a 240-base pair fragment of the PBP-2B gene (*pbp2b*) of penicillin-susceptible *S. pneumoniae* and two common *pbp2b* mutations present in penicillin-resistant *S. pneumoniae* in order to simultaneously identify the penicillin susceptibility of strains. The autolysin gene was identified in all 1062 clinical isolates of *S. pneumoniae* evaluated. In addition, 98.9% of 621 penicillin-susceptible isolates were shown to have DNA fragments amplified by the penicillin-susceptible primers, whereas 72.1% of 441 penicillin-resistant isolates were detected by the penicillin-resistant *S. pneumoniae* primers.⁵⁵⁷ A gene probe for the gene encoding the PsaA protein also has been developed on the basis of PCR assay. PsaA was confirmed to be present in representative strains of all 90 known (at that time) serotypes of *S. pneumoniae*. The specificity of the assay was verified by the lack of signal from analysis of heterologous bacterial species ($n = 30$) and genera ($n = 14$), including viridans group streptococci. The potential of the assay for clinical application was shown by its ability to detect pneumococci in culture-positive nasopharyngeal specimens.³⁹¹

While a wide variety of molecular methods have been developed for the diagnosis of pneumococcal disease, use of these methods to rapidly detect *S. pneumoniae* remains problematic, with assays such as those targeting the pneumolysin gene cross-reacting with other streptococcal species, while assays that target the autolysin and *psaA* genes appear to be more specific.^{4,90,368,420,528,608,40,303,493} The significance and clinical implications of *S. pneumoniae* DNA detected in clinical samples is therefore difficult to determine.⁶¹ The diagnosis of pneumococcal CAP has been improved by use of real-time PCR in blood and World Health Organization-validated serotype-specific serology.¹³³ A study using these methods to diagnose CAP in children hospitalized for CAP in Belgium after implementation of PCV7 increased the diagnosis of a pneumococcal etiology from 12% to 74%, with nonvaccine-serotypes accounting for the majority of cases.

Susceptibility Testing

Susceptibility testing of pneumococci has been well standardized, and testing can be performed by determination of the minimal inhibitory concentration (MIC) and, for selected agents, by disk diffusion.³⁵⁶ MICs can be performed by macrodilution or microdilution in cation-supplemented Mueller-Hinton broth enhanced with 5% whole defibrinated sheep or horse blood or 5% percent lysed and centrifuged horse blood.¹⁰³ If sulfonamides are tested, only the latter supplement should be used to avoid the presence of sulfonamide antagonists. MICs also can be determined by dilution in Mueller-Hinton agar supplemented as just described. Many systems based on frozen or dried microdilution trays are available commercially and used extensively for surveillance testing.²⁶⁵ As with any system, commercial microdilution panels should be validated and used with appropriate quality controls. Another method for determination of MICs, the E-test (bioMérieux), is much simpler to use than are the other methods for MIC determination. Evaluation of the E-test has shown that this method generally is reliable, although problems are encountered with some agents because acidification of the medium occurs during incubation of the plates in CO₂, which is

required to ensure the growth of clinical isolates. Agents particularly affected are macrolides and some quinolones.

Disk diffusion also has been standardized well for testing pneumococci against selected agents. Distinction between susceptible and resistant strains is accomplished readily by using the current Clinical and Laboratory Standards Institute method involving macrolides, tetracycline, chloramphenicol, trimethoprim-sulfamethoxazole, and clindamycin.^{103,264} For testing penicillin and other β -lactams, disk diffusion is used best as a screening method with 1- μ g oxacillin disks that have a susceptible cutoff zone of 20 mm or larger. Strains with zones of 20 mm or larger are fully susceptible to penicillin and other β -lactams. However, strains with zones that are less than 20 mm need to have MICs of penicillin and other appropriate β -lactams determined. Penicillin-susceptible strains with MICs of 0.06 μ g/mL usually screen out with resistant strains.

Although interpretative categories for clarifying the significance of MIC values are available, many limitations to the currently available Clinical and Laboratory Standards Institute pneumococcal breakpoints exist, particularly for agents that can be administered in multiple-dosing regimens and by multiple routes of administration and that are used for infections in different body sites. Breakpoints for parenteral β -lactam agents generally are based on the use of agents in meningitis, whereas those of oral β -lactam agents are based on nonmeningeal infections, such as otitis media.^{103,264} Nonmeningeal breakpoints for some parenteral β -lactam agents were introduced in 2002, which to some extent will avoid the use of non- β -lactam agents for serious nonmeningeal pneumococcal infections. These breakpoint changes classify strains previously interpreted as intermediate in sensitivity to penicillin G, cefotaxime, and ceftriaxone as susceptible if the agents are administered parenterally to treat pneumonia and other nonmeningeal infections. Pharmacokinetic and pharmacodynamic parameters have been shown to correlate with clinical outcome and offer a more rational approach to predicting antimicrobial efficacy and determining clinically relevant susceptibility breakpoints.^{111,120,268,271}

The activity of antimicrobial agents against penicillin-susceptible, penicillin-intermediate, and penicillin-resistant pneumococci, based on the original penicillin breakpoints (susceptible, ≤ 0.06 μ g/mL; intermediate, 0.12–1 μ g/mL; resistant, ≥ 2 μ g/mL), are shown in Table 85.3.²⁶⁷ There is considerable variation in antimicrobial susceptibility between pneumococcal serotypes, and the in vitro activity of selected antimicrobial agents against a collection of 891 pneumococci collected in 2008 from 22 centers in the United States is shown in Table 85.4 for all isolates and for the 11 predominating serotypes.²⁶⁹ All serotype 7F isolates were susceptible to all agents tested, as were greater than 95% of serotype 3 isolates. In contrast, many isolates of serotypes 19A, 6C, and 19F were multidrug resistant. Serotypes and antimicrobial susceptibility of pneumococci isolated from blood or lower respiratory tract specimens from hospitalized patients in the United States (all age groups) during 2011 to 2012 ($n = 1190$) were compared with those from a similar study performed in 2008 ($n = 694$).³⁷⁷ Percentages of PCV7 types were 6.3% and 4.9% in 2008 and 2011 to 2012, respectively, and the most common PCV7 serotypes (19F and 6B) comprised only 3.7% and 4.0% of all isolates from both periods, respectively. PCV13 serotypes represented 42.9% of isolates in 2008 and 30.1% in the second period. Non-PCV13 serogroups/serotypes 23A, 15B/15C, 7C, 8, and 31 increased. Penicillin nonsusceptibility rates (using parenteral nonmeningitis breakpoint of ≥ 4 μ g/mL) were 9.6% and 38.9%, respectively.

Antibiotic Resistance

Resistance to β -Lactam Drugs

Widespread resistance to β -lactam and other drug classes has evolved in the most common pathogens, including *S. pneumoniae*. Although pneumococci are naturally transformable organisms, β -lactamase production never has been described in this organism. Instead, a much more complex resistance mechanism has evolved in *S. pneumoniae* that is mediated by sophisticated restructuring of the targets of the β -lactams, the PBPs, and by other newly described mechanisms.²²² The PBP targets in penicillin-resistant strains of *S. pneumoniae* are modified, low-binding affinity versions of the native PBPs. PBP targets may be modified by mutation or by transformation and homologous recombination with DNA from the PBP genes of viridans streptococci. The level of resistance

is determined by how many and to what extent targets are modified.⁹³ Restructuring of PBPs is mediated by stepwise alterations in PBPs. The high-molecular-weight PBPs—types 1A, 2X, and 2B—that usually are detected in *S. pneumoniae* are involved in transpeptidase activity and play an important role in resistance.²²² Alterations in PBP-2B are associated with low-level resistance to penicillin, and alterations in PBP-2X mediate low-level resistance to cephalosporins. The additional alterations in PBP-1A raise penicillin MICs to 1 µg/mL or greater and cefotaxime MICs to 0.5 µg/mL or greater. Genomic comparison between *S. pneumoniae* and commensal *S. mitis* and *S. oralis* strains has documented the mosaic nature of PBPs among these species, with pneumococci acquiring their altered PBP genes from *S. mitis* and *S. oralis*.²²¹ Many other mosaic gene clusters not associated with penicillin resistance also have been found.¹⁸⁷ The capacity to produce branched cell wall stem peptides encoded by altered *murM* and *murN* genes, as well as altered

PBPs, is required for expression of penicillin resistance in *S. pneumoniae*.¹⁶⁹ The *fibA* and *fibB* genes, which are homologous to the *Staphylococcus aureus femA/B* genes required for expression of methicillin resistance in this organism, encode proteins involved in the formation of interpeptide bridges and also are required for expression of PBP-mediated penicillin resistance.⁵⁸⁸ Other mechanisms of β-lactam resistance have been described in laboratory mutants and in a clone of Hungarian pneumococcal strains with notably high levels of β-lactam resistance (penicillin MIC, 16 µg/mL; cefotaxime MIC, 4 µg/mL).^{222,519}

Resistance to Non-β-Lactam Drugs

The molecular and genetic mechanisms of resistance to macrolides, chloramphenicol, tetracycline, fluoroquinolones, and trimethoprim-sulfamethoxazole in *S. pneumoniae* also have been determined. Resistance genes for several agents are carried on a transposon, Tn1545.¹¹⁰ It confers

CLSI, Clinical and Laboratory Standards Institute; SXT, trimethoprim-sulfamethoxazole.

resistance to three antimicrobial classes—kanamycin (*aphA-3*), macrolide-lincosamide-streptogramin B-type antibiotics (*ermB*), and tetracycline (*tetM*). This transposon has been conjugated and transposed to the chromosome of *Enterococcus faecalis*, oral streptococci, and *Listeria monocytogenes*. The properties of this transposon account for the sudden emergence, rapid dissemination, and stabilization of resistance to multiple antibiotics in *S. pneumoniae* in the absence of plasmids.

Resistance mechanisms include the production of chloramphenicol acetyltransferase, an enzyme capable of catalyzing the conversion of chloramphenicol to nonfunctional derivatives. Chloramphenicol acetyltransferase is encoded by a chloramphenicol acetyltransferase (*cat*) gene identical to the *cat* gene from the *S. aureus* plasmid pC194. Tetracycline resistance occurs through ribosomal protection encoded by the genes *tetM* and *tetO*. The *tetM* and *tetO* proteins are thought to cause tetracycline to be released from the ribosome. Resistance to fluoroquinolones primarily involves mutations in the DNA gyrase gene *gyrA* and in the topoisomerase IV genes *parC* and *parE*, as well as an efflux mechanism that affects some fluoroquinolones. Resistance to trimethoprim is mediated through a single amino acid substitution in the chromosomal dihydrofolate reductase gene of *S. pneumoniae*, which is thought to disrupt the bond with trimethoprim without affecting the action of dihydrofolate reductase. Sulfonamide resistance appears to result from repetitions of one or two amino acids in the chromosomal dihydropteroate synthase.⁵⁹⁷

Two major mechanisms have been described for resistance to erythromycin. Co-resistance to macrolides, clindamycin, and streptogramin B-type antibiotics is a result of modification of the ribosome through methylation of an adenine residue in domain V of the 23S rRNA. Methylation is encoded by a methylase gene, *ermB* (previously called *ermAM*). Resistance to 14- and 15-membered macrolides (erythromycin, azithromycin, and clarithromycin) but not to 16-membered macrolides (roxithromycin, josamycin, and spiramycin), ketolides, or clindamycin is a result of efflux of the antibiotic from the cell; such resistance is encoded by the gene *mefE* in *S. pneumoniae* and appears to be emerging rapidly as the predominant mechanism of resistance to erythromycin in many countries.¹⁸⁷ Other macrolide resistance mechanisms that have been described include mutations in position 2059 of the 23S rRNA and in genes encoding ribosomal protein L4.⁵³⁷

Vancomycin Tolerance

Although vancomycin resistance has not been described in pneumococci, antibiotic tolerance, or the ability of bacteria to survive but not grow in the presence of antibiotics, has been described. It has been shown

to be caused by loss of function of the VncS histidine kinase of a two-component gene expression sensor-regulator system in *S. pneumoniae* that produces tolerance to vancomycin and other classes of antibiotics.⁴⁰⁹

Evolution of Antibiotic Resistance

Pneumococci initially were susceptible to many antimicrobial agents, but they became resistant with varying degrees of rapidity to many of these agents. The earliest example was the development of resistance to optochin (ethylhydrocupreine) when this agent was used experimentally in mice in the early part of the 20th century. With the introduction of sulfonamides in 1939, pneumococci similarly exhibited an ability to acquire resistance in experimental infections in mice, as well as in a human case of meningitis.³¹⁰ Sulfonamide resistance was identified sporadically thereafter, and a trimethoprim-sulfamethoxazole-resistant strain was recognized first in 1972. Trimethoprim-sulfamethoxazole resistance subsequently has become widespread in virtually all serotypes throughout the world, including developing countries, and resistance to this agent is greater than that to any other antimicrobial class worldwide.²⁴⁵ Tetracycline resistance emerged in the 1960s and chloramphenicol resistance in 1970. However, little attention was paid to the development of resistance in this species until 1977, when isolates resistant to several antimicrobial classes—including penicillins, chloramphenicol, tetracyclines, macrolides, clindamycin, and trimethoprim-sulfamethoxazole—were detected in South Africa.^{22,270}

Subsequently, multiresistant clones of pneumococci have spread throughout many regions of the world. Noteworthy is that multiresistant clones are confined mostly to serotype 14 and serogroups 6, 9, 19, and 23.¹³¹ Whereas resistance to penicillins occurs in a stepwise fashion and in many cases can be overcome by using β -lactams with appropriate pharmacokinetics, resistance to other drug classes usually is absolute, and distinct populations of strains are found to be susceptible and resistant to agents such as macrolides, clindamycin, tetracyclines, trimethoprim-sulfamethoxazole, and chloramphenicol. Unlike enterococci, resistance to vancomycin has not developed in pneumococci yet, although vancomycin-tolerant strains have been detected.^{46,242}

Cross-resistance among *S. pneumoniae* to macrolides and other classes of antibiotics usually increases with increasing MICs to penicillin²⁶⁸ (Fig. 85.12). Whereas only 6% of penicillin-susceptible pneumococci are resistant to macrolides and 14% to trimethoprim-sulfamethoxazole, approximately half of the penicillin-intermediate isolates were resistant to these agents. In the case of penicillin-resistant strains, three-quarters were resistant to macrolides, 90% to trimethoprim-sulfamethoxazole,

FIG. 85.12 Pneumococci often are resistant to several drug classes, and cross-resistance to macrolides and other classes of antibiotics increases as minimal inhibitory concentrations of penicillin increase. TMP-SMX, trimethoprim-sulfamethoxazole. (From Jacobs MR. Antimicrobial-resistant *Streptococcus pneumoniae*: trends and management. *Expert Rev Anti Infect Ther*. 2008;6:619–35.)

and 28% to clindamycin. However, this pattern is not the case in all countries, and at least one multiresistant clone resistant to chloramphenicol, tetracycline, erythromycin, clindamycin, and trimethoprim-sulfamethoxazole has remained susceptible to penicillin.^{135,536}

Strains of *S. pneumoniae* were exquisitely susceptible to penicillin (MICs of 0.01 to 0.03 µg/mL) when this agent initially was used clinically in the 1940s and 1950s, and this MIC range is referred to as the baseline activity of penicillin against “wild-type” *S. pneumoniae*.²⁶⁴ Evolution of resistance to this class of agents was noted first when a few strains of *S. pneumoniae* were isolated in the 1960s in Australia and New Guinea. These strains had decreased susceptibility to penicillin, with MICs of 0.1 to 0.25 µg/mL, approximately 10-fold higher than the MICs of baseline strains. Strains with penicillin MICs of 2 to 4 µg/mL, approximately 100-fold higher than baseline strains, were isolated in South Africa in 1977; subsequently, strains with even higher MICs (16 µg/mL, approximately 1000-fold higher than baseline strains) were described in Hungary.⁵¹⁹ Pneumococci conventionally are classified as penicillin-susceptible if the MICs are 0.06 µg/mL or less, intermediate if the MICs are 0.12 to 1.0 µg/mL, and resistant if the MICs are 2.0 µg/mL or greater. This classification is useful mainly in characterizing strains as fully susceptible to β-lactams if susceptible or as having decreased susceptibility if intermediate or resistant. Strains with such decreased susceptibility are better referred to as β-lactam drug-challenged because the mechanism of resistance can be overcome if the pharmacokinetics of the β-lactam drug used in serum or at the site of infection exceeds the MIC for 40% to 50% of the dosing interval.¹¹² Similar variations in MIC ranges are seen with all β-lactams, although MIC ranges for many β-lactams are much higher than that for penicillin itself. Agents such as ampicillin, amoxicillin, cefotaxime, and ceftriaxone have MIC ranges similar to that of penicillin, whereas agents such as cefazolin, cefaclor, cefprozil, ceftazidime, and cefixime have much higher MIC ranges. For example, the baseline activity of cefaclor against *S. pneumoniae* is 0.5 to 1 µg/mL, which is a concentration approximately 20- to 30-fold higher than that required for penicillin to inhibit the most susceptible strains. Changes in susceptibility that occur over the course of time were illustrated in a study of recent versus archived otitis media strains. In this study, the MIC₉₀ for cefaclor against archived isolates was 1 µg/mL, whereas the MIC₉₀ against recent isolates was greater than 64 µg/mL.²⁶⁶ A few agents, such as imipenem and meropenem, have slightly lower MIC ranges than those of penicillin. The proportion of pneumococci that are penicillin susceptible, intermediate, and resistant vary considerably throughout the world.

Resistance to macrolides in strains of *S. pneumoniae* was noted first in 1964 and was detected sporadically in the United States until it became widespread in the latter half of the 1990s.^{245,259,310} The baseline activity of macrolides (0.03 µg/mL) and MIC distributions (1000-fold

concentration range, 0.03 to >32 µg/mL) against *S. pneumoniae* are somewhat similar to those of penicillin. The MIC distribution of macrolides is trimodal, with strains being exquisitely susceptible (erythromycin MIC ≤0.03 µg/mL) or highly resistant (erythromycin MIC ≥32 µg/mL) or demonstrating low-level resistance (MICs of 1–16 µg/mL).¹⁶³ These distributions closely correlate with macrolide ribosomal methylase and efflux resistance mechanisms. The prevalence of macrolide resistance and reports of clinical failure resulting from strains with efflux and ribosomal methylase resistance mechanisms continue to increase. Some authors, however, have argued that isolates with efflux-mediated resistance could be susceptible to the high intracellular concentrations that these agents achieve in phagocytic cells and in epithelial lining fluid of the alveoli.¹⁴ However, no clinical or animal data support these arguments for extracellular pathogens such as *S. pneumoniae*, whereas considerable clinical and animal data support the use of current breakpoints.^{43,111,112,385} The rising incidence of macrolide-resistant pneumococci was directly proportional to the increasing use of macrolides in various communities and age groups.^{184,259,440}

Strains with multiple antibiotic resistance have greater selective advantages than do strains resistant to just one antibiotic because the opportunity for positive selection is increased as the number of drug classes to which isolates are resistant increases.³¹¹ Exposure to different classes of antibiotics allows more opportunity for selective advantage to a multiple antibiotic-resistant organism than to a monoresistant strain, which must wait to encounter the one antibiotic to which it is resistant and is likely to be killed by agents of other antibiotic classes. Thus, the increasing prevalence of antibiotic-resistant pneumococci is associated with the increasing prevalence of multidrug-resistant strains. Therefore, one is not surprised that the use of one class of antibiotics (mainly macrolides and trimethoprim-sulfamethoxazole) can be associated with an increase in resistance to other classes of antibiotics (mainly β-lactam drugs).^{3,23,202,440} Many authorities now think that antibiotic agents such as the newer macrolides (e.g., clarithromycin and azithromycin) and trimethoprim-sulfamethoxazole are stronger promoters of antibiotic resistance among *S. pneumoniae* strains than are the β-lactam drugs.^{23,202,440} Researchers also have suggested that among the β-lactam drugs, cephalosporins are stronger promoters of resistance in *S. pneumoniae* than are the aminopenicillins.^{184,488} Although many strains are resistant to tetracyclines and macrolides, they are susceptible to the new tetracycline derivatives, the glycylcyclines, as well as to streptogramins, ketolides, glycopeptides, oxazolidinones, and rifampin. Many strains are resistant to trimethoprim-sulfamethoxazole worldwide, with more than 40% being resistant in the United States. Fluoroquinolones with antipneumococcal activity (e.g., gatifloxacin, levofloxacin, moxifloxacin) are active against most strains of *S. pneumoniae*. However, in several countries where fluoroquinolones have been prescribed widely, clinically relevant levels of resistance have been described.^{95,245} No doubt, antibiotic resistance will continue to evolve and challenge us.

HOST DEFENSES

Although anticapsular antibody is the most prominent protective mechanism against pneumococcal infection, many host responses to infection occur and many other factors are associated with protection against disease.³⁹⁹ Pneumococcal infection and disease have been modeled in several animal species. Most are models of sepsis arising from intravenous or intraperitoneal inoculation of bacteria, and only a few were designed to study disease arising from intranasal infection. Chinchillas provide the only animal model of middle ear pneumococcal infection in which the disease can be produced by very small inocula injected into the middle ear or intranasally. This model, developed at the University of Minnesota in 1975, has been used to study pneumococcal pathogenesis at a mucosal site, the immunogenicity and efficacy of pneumococcal capsular polysaccharide vaccine antigens, and the kinetics and efficacy of antimicrobial drugs.¹⁹³

Anticapsular Serum IgG Antibody

IgG to the capsular polysaccharide of *S. pneumoniae* is thought to provide the greatest degree of protection against systemic pneumococcal disease

and limited protection against colonization. The reference method for measurement of antibody is the opsonophagocytosis assay, which involves serial dilutions of serum, viable pneumococci, complement, and viable PMNs incubated together for 1 hour.⁴⁷² An infant mouse assay system for assessment of protective concentrations of human serum pneumococcal anticapsular antibodies correlated well with opsonophagocytic titer but not with naturally occurring IgG antibody concentrations or IgG produced in response to nonconjugated polysaccharide vaccines, as determined by ELISA.^{283,404} However, the ELISA method of serotype-specific antibody assay with absorption of cross-reacting antibody to cell wall polysaccharides does correlate well with protection after vaccination with conjugated vaccine, and it is the method used most commonly to predict serotype-specific immunity.^{21,561,562}

The development of a phagocytosis assay based on flow cytometry has not overcome the limitations of the ELISA method and is inferior to the opsonophagocytosis method.²⁷⁶ Investigation of polymorphisms in the variable region of IgG that affect protective function has indicated that the capsular polysaccharide antibody repertoire in adults is derived from memory B-cell populations that have switched class and undergone extensive hypermutation.³⁵⁵ Functionally disparate anticapsular polysaccharide antibodies can arise within individuals both by activation of independent clones and by intraclonal somatic mutation, which illustrates the complexity of assaying and interpreting serum capsular polysaccharide antibody levels.

Anticapsular IgA Antibody

The role of IgA in the control of invasive mucosal pathogens such as *S. pneumoniae* is understood poorly. Human pneumococcal capsular polysaccharide-specific IgA initiates dose-dependent killing of *S. pneumoniae* in the presence of complement and phagocytes. The majority of specific IgA in serum is of the polymeric form, and the efficiency of killing initiated by this polymeric form exceeds that of monomeric IgA-initiated killing. In the absence of complement, specific IgA induces minimal bacterial adherence, uptake, and killing. Killing of *S. pneumoniae* by resting phagocytes with immune IgA requires complement, predominantly via the C2-independent alternative pathway, which, in turn, requires factor B but not calcium. Pneumococcal capsule-specific IgA may have distinct roles in effecting the clearance of pneumococci in the presence or absence of inflammation, and the polymeric form may control pneumococcal infections locally and after the pathogen's entry into the bloodstream by several mechanisms.²⁷⁴

Phagocytosis and Leukocyte IgG Receptors

IgG-mediated phagocytosis by PMNs is the main defense against *S. pneumoniae*. Two leukocyte IgG receptors, FcγRIIa and FcγRIIb, are expressed constitutively on PMNs. Blocking experiments have shown that FcγRIIa is crucial for opsonophagocytosis of serum-opsonized *S. pneumoniae*. In adults, serum-induced phagocytic activity depends mainly on antipneumococcal IgG2 antibodies.⁴⁷¹ However, in infants and young children, the main response to pneumococcal conjugate vaccines occurs in the IgG1 subclass.^{21,571} Investigators have suggested that IgG1 subclass antibodies are at least as highly functional as IgG2.¹⁵⁸ Recruitment and function of neutrophils also are important host defenses. In a pneumococcal infection model in immunocompetent and immunodeficient mice intranasally infected with *S. pneumoniae* type 2, immunocompetent BALB/c mice were resistant and immunodeficient CBA/Ca mice were susceptible to infection. BALB/c mice recruited significantly more neutrophils in the lungs, and inflammatory lesions were visible much earlier than in CBA/Ca mice.¹⁹⁷

Antibodies to Surface Proteins and Pneumolysin

PspA, PsaA, and pneumolysin are common to virtually all pneumococcal isolates. The development of antibodies to PspA, PsaA, and pneumolysin as a result of pneumococcal infection and carriage in young children was determined by measurement of serum antibodies to these proteins by ELISA in children at ages 6, 12, 18, and 24 months and in their mothers. All age groups were shown to produce antibodies to the three proteins, which increased with age and were associated strongly with pneumococcal exposure as a result of carriage or AOM.⁴⁵⁶ IgA to PspA, PsaA, and pneumolysin has been detected by ELISA in the saliva of

children aged 6 to 24 months.⁵¹¹ This finding was associated with pneumococcal carriage and otitis media.

Serum antipneumolysin IgG at the time of hospital admission has been found to be higher in patients with nonbacteremic pneumococcal pneumonia than in those with bacteremic pneumococcal pneumonia or uninfected control subjects.⁴⁰³ Serum antipneumolysin IgG levels also rose significantly during convalescence in patients with bacteremic pneumonia, and the levels attained were equal to those observed in nonbacteremic patients. Children aged 6 to 24 months were shown to produce antibodies to pneumolysin, and antibody concentrations increased with age and were associated strongly with pneumococcal exposure, whether by carriage or infection such as AOM.⁴⁵⁶ Infants also have been shown to mount a specific antibody response to pneumolysin during AOM.⁴⁵⁷

Defense Mechanisms of the Spleen

The spleen is the principal organ that clears pneumococci from the bloodstream.^{399,326} Opsonized particles are removed from the circulation by the liver, but with decreasing opsonization, the spleen increasingly assumes the role of clearance. The slow passage of blood through the spleen and the prolonged contact time with reticuloendothelial cells in the cords of Billroth and the splenic sinuses allow time for the removal of nonopsonized particles. Overwhelming pneumococcal infection occurs in children and adults whose spleens have been removed or do not function normally. Pneumococcal disease progresses so rapidly in such individuals that pneumonia is not detectable clinically or by chest radiographs, although it is seen at autopsy. The increase in the incidence of pneumococcal bacteremia and meningitis in children with sickle-cell disease is due largely to splenic dysfunction. Splenectomy also results in a marked, sustained elevation in risk of severe infection due to *S. pneumoniae* in HIV patients.⁴⁴⁵

Vitamin A

The association of nasopharyngeal colonization with *S. pneumoniae* and vitamin A supplementation in infants in an area with endemic vitamin A deficiency in southern India showed that neonatal vitamin A supplementation delayed the age at which colonization occurs. Therefore, it may play a role in lowering morbidity rates associated with pneumococcal disease.¹⁰⁷

C-Reactive Protein

C-reactive protein (CRP) is a normal constituent of human serum that is synthesized by hepatocytes and induced by proinflammatory cytokines. The function of this acute-phase reactant includes activation of complement and enhancement of opsonophagocytosis. CRP binds to phosphorylcholine, a constituent of eukaryotic membranes that also is found on the cell surface of the major bacterial pathogens of the human respiratory tract, including *S. pneumoniae* and *H. influenzae*. CRP is present in inflamed (0.17–42 μg/mL) and uninfamed (<0.05–0.88 μg/mL) secretions from the human respiratory tract in sufficient quantities to have an antimicrobial effect. In addition, the CRP gene was expressed in human respiratory epithelial cell cultures. The complement-dependent bactericidal activity of normal nasal airway surface fluid and sputum was abolished when the secretions were pretreated to remove CRP. Human respiratory epithelial cells are capable of expressing CRP, which may contribute to bacterial clearance in the human respiratory tract.²⁰⁶

Platelet-Activating Factor Receptors of Airway Epithelial Cells

Adherence of pneumococci to cultured human tracheal epithelial cells increased after exposure to acid and decreased after exposure to a specific inhibitor of the receptor for platelet-activating factor.²⁶¹ Exposure to acid thus may stimulate the adherence of *S. pneumoniae* to airway epithelial cells via increases in platelet-activating factor receptors. The clinical significance of these findings is not clear.

Cytokines

Polymorphonuclear granulocytes, which provide a major defense against *S. pneumoniae* infection, are attracted to and activated by various cytokines, including IL-1β, IL-6, TNF-α, IL-8, IL-10, IL-12, interferon-γ,

and granulocyte-macrophage colony-stimulating factor.²⁸ The inflammatory response in bacterial meningitis also is mediated by TNF- α and IL-1, which are produced in the subarachnoid space by cells such as leukocytes, astrocytes, and microglia.⁴²⁴ Inoculation of pneumococcal cell wall components directly into the CSF of rabbits also results in the induction of an inflammatory response with pleocytosis and increased levels of CSF TNF- α and IL-1.²⁰⁸ Both TNF- α and IL-1 β increase mucosal adhesion of pneumococci to tracheal epithelium in a chinchilla trachea whole-organ perfusion model.⁵⁵³ Induction of type I interferon response in the lung has been postulated to be a key factor in early progression of invasive disease. In a mouse model, a serotype 1 strain infection progressed beyond the lung during development of IPD.²⁵⁸ The pneumococcal virulence factor associated with this type I interferon induction has not been described.

L-Ascorbic Acid (Vitamin C)

Degradation of the connective tissue component hyaluronic acid by the hyaluronate lyase produced by *S. pneumoniae* is inhibited competitively by L-ascorbic acid (vitamin C).³⁴³ One L-ascorbic acid molecule was found to bind to the active site of the enzyme. The high concentration of L-ascorbic acid in human tissues probably provides a low level of natural resistance to pneumococcal invasion by this mechanism.

Leukotrienes

Leukotrienes are produced by macrophages and are considered important for antibacterial defense in the lung. Leukotrienes comprise a group of highly potent lipid mediators synthesized by the enzyme 5-lipoxygenase. Multidrug-resistance protein 1 (mrp1) is a transmembrane protein responsible for the cellular extrusion of leukotrienes from macrophages. In a mouse pneumonia model, mrp1-deficient mice display diminished growth of pneumococci in the lungs and low mortality by a mechanism that involves increased release of leukotriene B₄.⁴⁹⁵ Pneumococci also induce the production of leukotrienes in the middle ear, which has been related to up-regulation of two genes that govern the lipoxygenase pathway.³⁴⁸

Human Alveolar Macrophage Binding and Phagolysosomes

Human alveolar macrophages are the major resident phagocytic cells of the lung. After contact with macrophages, bacteria enter phagosomes, which gradually acquire the characteristics of terminal phagolysosomes, with incorporation of lysosome-associated membrane protein. Opsonization with serum containing immunoglobulin resulted in significantly greater binding of pneumococci to macrophages than did opsonization with immunoglobulin-depleted serum.²⁰³ Binding, intracellular localization, and killing of pneumococci by macrophages all are increased significantly by opsonization with serum containing immunoglobulin, complement, or both.

Intracellular Killing

Once pneumococci undergo phagocytosis by “professional” phagocytes (leukocytes and macrophages), they are killed.³⁹⁹ However, researchers have shown that pneumococci can enter and survive inside A549 cells, a human lung alveolar carcinoma (type II pneumocyte) cell line.⁵⁴⁰ Not all clinical *S. pneumoniae* isolates were capable of penetrating these cells, and the presence of a polysaccharide capsule also reduced their capacity to penetrate A549 cells significantly. The intracellular activity of various antibiotics against pneumococci in A549 cells showed that, in the presence of antibiotics for 18 hours, more than 98% of the A549 cells were viable and less than 3% of the pneumococci that initially were phagocytosed could be detected intracellularly after exposure to peak serum concentrations of penicillin G, azithromycin, moxifloxacin, trovafloxacin, rifampin, and telithromycin.³⁶⁶

In the absence of antibiotics, pneumococci were phagocytosed efficiently but then paradoxically went on to kill all the A549 cells within 18 hours. The clinical significance of these findings is unknown.

Complement

The second component of complement (C2) is an important factor associated with host defense against encapsulated organisms. Homozygous deficiency of C2 is the deficiency of complement most commonly

inherited. Although C2 deficiency can be asymptomatic, patients usually have either autoimmune disease or recurrent pyogenic infection caused by encapsulated bacteria such as *S. pneumoniae*, *H. influenzae* type b (Hib), and *Neisseria meningitidis*. An association between C2 deficiency and IgG subclass deficiency also has been described.²⁹ *S. pneumoniae* challenge of mice deficient in the third component of complement (C3) results in a 2000-fold increase in organism load in the bloodstream in comparison to controls.¹⁰² Binding of pneumococcal CbpA to epithelially produced C3 results in adhesion of pneumococci to type II pulmonary epithelial cells. CbpA-deficient pneumococcal mutants and lysates therefore fail to bind C3 and demonstrate a moderate decrease in adhesion to type II pulmonary epithelial cells, thus confirming the interaction of CbpA and C3 in adhesion.⁵¹⁸

Polymeric Immunoglobulin Receptor

pIgR plays a crucial role in mucosal immunity against microbial infection by transporting polymeric immunoglobulins such as IgA across the mucosal epithelium. Polymeric IgA consists of two IgA molecules joined by a small polypeptide J chain. The J chain shows high affinity for the glycoprotein pIgRs of epithelial cells, which are responsible for externalization of polymeric IgA across cell membranes.²⁸⁰ However, pIgR also can act as a “Trojan horse” and participate in the pathogenesis of invasive pneumococcal disease as pIgR binds to a major pneumococcal adhesin, CbpA.⁶²⁰ Expression of pIgR in human nasopharyngeal cells greatly enhances pneumococcal adherence and invasion; this effect is abolished either by insertional knockout of CbpA in pneumococci or by antibodies against either pIgR or CbpA.

Basic Fibroblast Growth Factor

Basic fibroblast growth factor is a neurotrophic factor in the central nervous system that is expressed at high levels in response to seizure or stroke. It also occurs in pneumococcal meningitis, as shown in experimental bacterial meningitis in mice and in children with bacterial meningitis.²⁵⁶ Patients with meningitis in whom major sequelae or death occurred had much higher levels of CSF basic fibroblast growth factor than did those who survived. In patients with bacterial meningitis who survived, basic fibroblast growth factor decreased significantly in CSF after 24 to 50 hours of administration of antibiotic therapy. However, its biologic role in the pathogenesis of bacterial meningitis is not known.

Granulocyte Colony-Stimulating Factor

In a limited study of 22 nonneutropenic adult patients with pneumococcal meningitis, granulocyte colony-stimulating factor (G-CSF), in addition to cefotaxime and dexamethasone, was administered subcutaneously for 6 days. All patients survived, and in only one patient did a complication develop (bilateral hearing deficit). Improvement of inflammation indices in CSF was rapid.¹³² However, controlled clinical trials are needed. In a rabbit meningitis model, G-CSF increased the percentage of granulocytes in blood but not in CSF and increased CSF TNF- α and IL-1 β concentrations.⁴⁹² However, G-CSF did not reduce the density of apoptotic neurons in the dentate gyrus of the hippocampus. A second study in a rabbit meningitis model used longer pretreatment with G-CSF and showed more positive results.⁴²³ G-CSF pretreatment attenuated meningeal inflammation and enhanced systemic killing of bacteria. Pretreatment with recombinant human G-CSF in a murine model of pneumococcal pneumonia resulted in improved survival with low, but not high, bacterial inocula. Therefore, the benefits of using G-CSF are limited, as pneumococci already have recruited large numbers of neutrophils in the lungs by this time.¹²⁸

Intracellular Signaling Pathways

Pneumococcal cell walls activate multiple intracellular signaling pathways in microglial brain cells, with induction of an outwardly rectifying K⁺ channel; suppression of the constitutively expressed inwardly rectifying K⁺ current; and release of TNF- α , IL-6, IL-12, and other inflammatory mediators.⁴⁴⁹ The presence of serum strongly facilitated these effects. The mechanisms involved in microglial activation by pneumococcal cell walls were different from those activated by gram-negative lipopolysaccharide.

Lactoferrin

Human lactoferrin is an iron-binding glycoprotein that is particularly prominent in exocrine secretions and leukocytes and also is found in serum, especially during inflammation. It is able to sequester iron from microbes and has immunomodulatory functions, including inhibition of both activation of complement and production of cytokines. Binding of human lactoferrin to the surface of *S. pneumoniae* depends entirely on PspA.²²⁰ Prevention of the binding of lactoferrin to pneumococcal PspA could be an important host defense mechanism.

Mannose-Binding Lectin

MBL is a key mediator of innate host immunity that activates the complement pathway and directly opsonizes some infectious pathogens. Mutations in three codons in the MBL gene have been identified, and individuals homozygous for a mutant genotype have very little or no serum MBL. In a study conducted in the United Kingdom of 229 patients in whom *S. pneumoniae* was isolated from sterile sites, 28 (12%) were homozygous for MBL codon variants versus only 18 of 353 (5%) controls (odds ratio, 2.59; 95% confidence interval, 1.39–4.83).⁴⁷⁹

Ficolin-2

Serotype 11E has been described among isolates previously typed as 11A.⁷³ Serotype 11A pneumococci express capsule beta-galactose-6-O-acetylation mediated by the capsule synthesis gene *wcjE*, while serotype 11E strains contain loss-of-function mutations in *wcjE* and completely lack expression of beta-galactose-6-O-acetylation.⁸⁶ Serotype 11E is rarely carried, but is a common invasive strain, suggesting that it survives better during invasion. This has been postulated to be associated with the innate host factor ficolin-2, an initiator of the lectin complement pathway leading to complement-dependent opsonophagocytosis. Low ficolin-2 binding to serotype 11A has been postulated to account for the low invasive potential of this serotype 11A.⁷³

CLINICAL SYNDROMES

The pneumococcus causes disease over the entire age spectrum from early-onset neonatal sepsis to pneumonia, IPD, and meningitis in geriatric patients. It is found frequently in the nasopharynx of children younger than 5 years, yet only a small fraction of colonized children develop either invasive disease syndromes or respiratory tract infection. New data from both animal and human studies suggest that colonization is associated with a mild inflammatory response within the nasopharynx that, in general, resolves spontaneously.^{287,604} In those children in whom the pneumococcus evades host defenses, it has the potential to cause local respiratory tract illnesses such as AOM, acute sinusitis, and nonbacteremic pneumonia or to enter the bloodstream and result in a spectrum of clinical syndromes, including bacteremia, sepsis, meningitis, or focal infections such as septic arthritis, osteomyelitis, endocarditis, soft tissue infection, or peritonitis. Infection may also spread directly to the central nervous system from the nasopharynx in children with cochlear implants and in children with basal skull fracture and CSF leak. Peritonitis is also reported, most often in children with nephrotic syndrome. Colonization of the genital tract in women is also reported and may be the source for early-onset sepsis in vulnerable newborns or spread through the fallopian tubes to the peritoneal cavity.

The clinical signs and symptoms of patients with pneumococcal infection can be nonspecific, reflective of the bacteremia/sepsis syndrome, or specific to the organ system involved. In general, bacteremia presents with high fever and temperatures that can exceed 40°C.³⁷ Pneumococcal pneumonia most often will present with fever, cough and tachypnea, and possibly chest pain when consolidation is also present.

Bacteremia and “Occult” Bacteremia

Unsuspected or “occult” bacteremia in children 3 to 36 months of age presenting with fever without evidence of toxicity or focal infection has been reported in up to 4% of febrile infants and toddlers in the era prior to the introduction of pneumococcal conjugate vaccines. Where clinical practice includes performance of blood cultures on febrile children with mild or moderate toxicity, bacteremia has been identified

from emergency or walk-in clinics as well as office practice settings.⁷⁵ In the United States, *S. pneumoniae* represented ~ 60% of pathogens identified in children well enough to be discharged home while *H. influenzae* type b (Hib) was identified in up to 25% of cases. This distribution was dramatically altered with the introduction of Hib conjugate vaccines, increasing the proportion of bacteremic cases from which *S. pneumoniae* was isolated from blood culture to 80% to 90%.^{12,307,602} Age less than 24 months and temperature greater than 39°C were the demographic and clinical features initially described that characterized the majority of children with “occult” pneumococcal bacteremia in US studies. Clinically, the risk of bacteremia increases with increasing temperature being greatest, with temperature greater than 40°C. Subtle clinical differences in alertness, color, quality of cry, hydration and responsiveness have been described in bacteremic children compared to otherwise similar febrile children.^{371,602,372} Laboratory studies reveal that elevated WBC counts above 15,000 per mm³, absolute neutrophil counts above 5,000 per mm³, or elevated erythrocyte sedimentation rate or procalcitonin¹⁷ are associated with increased risk of pneumococcal bacteremia, but each has a poor predictive value. These tests are best used as negative predictors, as a WBC count below 10,000 per mm³, normal absolute neutrophil count, or a normal erythrocyte sedimentation rate have negative predictive values that are near 99%.

The clinical significance of “occult” bacteremia in untreated children has been of considerable interest and debate, as some have argued “occult” bacteremia is the prologue to serious pneumococcal disease and others that it is primarily a self-resolving syndrome of less significance. Observational studies demonstrate spontaneous clearance in approximately one-third of cases and persistent signs or symptoms of illness in as many as two-thirds.³⁰⁷

Persistent bacteremia, even in those with persistent clinical illness, is not common even in the absence of antimicrobial therapy. However, the development of focal, presumed pneumococcal infection is not uncommon (Table 85.5). Temperature greater than 39°C at follow-up best correlates with the presence of persistent bacteremia or a new focus of infection. Persistent bacteremia and new focal infections were associated with higher temperature (mean, 38.8°C vs. 37.7°C), greater elevation in WBC count (18,900/mm³ vs. 14,900/mm³), age younger than 20 months, and no antibiotic treatment being prescribed during the initial visit.³⁷ Complications such as meningitis, pneumonia, cellulitis, periorbital cellulitis, and AOM are the most common focal infections reported at follow-up. Children in whom a lumbar puncture was performed at the initial presentation with fever without a focus, at the time of pneumococcal bacteremia as reflected by a positive culture of blood, have been reported to have a fivefold greater risk of having CSF pleocytosis and meningitis at follow-up.⁶⁰²

The role of antibiotics in initial management of the febrile child at risk of bacteremia for the prevention of serious focal complications is controversial. Bachur and Harper reported higher rates of persistent

TABLE 85.5 Outcome in Children With Pneumococcal Bacteremia Initially Managed at Home

Outcome	Number (%) of Children
Antimicrobial therapy at first visit	46 (47)
Improved at second visit	37 (79)
Not improved at second visit	9 (20)
Persistent bacteremia at second visit	2 (4)
Meningitis at second visit	2 (4)
No antimicrobial therapy at first visit	51 (53)
Improved at second visit	16 (31)
Not improved at second visit	35 (69)
Persistent bacteremia at second visit	13 (25)
Meningitis at second visit	2 (4)
TOTAL	97

From Teele DW, Marshall R, Klein JO. Unsuspected bacteremia in young children: a common and important problem. *Pediatr Clin North Am.* 1979;26(4):773-84.

clinical illness, persistent bacteremia, and focal infection in those not treated at the visit during which the blood culture was drawn compared to children receiving oral or parenteral therapy at the initial visit.³⁷ They also identified that only 1 of 8 patients with meningitis at follow-up returned prior to notification of a positive blood culture, suggesting that the practice of blood culture at initial visit enhances the early identification of at-risk children prior to clinical progression of disease, at least in some children. Whether this syndrome is unique to the United States or industrialized countries or is universal, including developing countries, is unclear largely because of differences in clinical practices in performing blood cultures in ambulant febrile children. The syndrome of “pneumococcal bacteremia without a focus” represented 61% to 70% of IPD in the United States in the pre-PCV era.⁶¹⁵

Comparable to reports from the United States, bacteremia without a focus, defined as a positive blood culture with no obvious focus after clinical and laboratory evaluation, was identified in 179 (70.5%) cases at a Canadian hospital in Alberta.³²⁹ Of those cases, 40% admitted to the hospital and 89% of those not admitted to the hospital did not have a focus of infection. Of the cases, 29% had focal infection; 8% percent had meningitis, almost 10% had pneumonia, 5.5% had periorbital cellulitis, and 6% had other clinical syndromes. Few cases were identified in the first 90 days of life, with the majority occurring in children between 3 and 36 months. Comorbid illness, primarily cardiac, respiratory, and neurologic conditions, was present in 21.6% of hospitalized children compared to 3.8% of those managed as an outpatient. The overall mortality rate was low at 0.7%. In other industrialized countries, primarily Europe, a low proportion of IPD is characterized as bacteremia without a focus (18–20%). In developing countries, the proportion is even lower (~1%).^{330,418,503}

Reports from cities such as Bangkok suggest that the “benign” nature of bacteremia without a focus is not a universal observation. In a hospital-based study in Bangkok, IPD without a focus was associated with 23% mortality rate, which was especially high in children with comorbid conditions.⁵¹³ These reports suggest that the syndrome IPD without a focus is different in severity and associated complications in Thailand compared to that described in the United States and Canada, with a large proportion of cases developing pneumonia or meningitis and high death rates during the initial few days of hospitalization. Earlier age of onset, nutritional status, comorbid conditions, or genetic factors may result in a different syndrome with more rapid progression of pneumococcal bacteremia and reduced likelihood of spontaneous clearance than the slower progression and relatively high rate of spontaneous resolution described in US children. Yildirim reported that during the years 2007 through 2009, bacteremia without any focus was the most common clinical presentation among children younger than 24 months (46.9% of all cases), whereas the majority of the cases in children older than 24 months presented as bacteremic pneumonia (45.9%).⁶¹²

Pneumococcal Sepsis With Purpura

Sepsis, characterized by hypotension and even purpura that mimics meningococcemia, is also reported with pneumococcemia (Fig. 85.13). It has been observed most often in children with sickle-cell anemia and in asplenic children, although it has also been reported in children with immunodeficiency as well on rare occasions in otherwise healthy children. Unlike meningococci, pneumococci do not produce an endotoxin. However, pneumococcal autolysin has been proposed as a potential mechanism. This glycan-teichoic acid fragment released from the bacterial cell wall has produced purpura when injected into monkeys and mice.^{97,234}

Acute hemorrhagic edema in association with pneumococcal sepsis has also been described, possibly suggesting a vasculitic mechanism.³⁹²

Pneumococcal Meningitis

S. pneumoniae has become the most common bacterial cause of bacterial meningitis in most countries following the introduction of *H. influenzae* type b conjugate vaccines, as well as the falling incidence of meningococcal disease in North and South America and Europe, in part as a result of meningococcal C conjugate vaccine programs. Although meningitis is a less common presentation of IPD in children compared with bacteremia, sepsis, and pneumonia, the case-fatality rates are high (6–54%) and neurologic morbidity is frequent in survivors (0–50%).^{214,435}

FIG. 85.13 *Streptococcus pneumoniae* sepsis with purpura fulminans in a child who had undergone splenectomy for refractory idiopathic thrombocytopenic purpura. (From American Academy of Pediatrics. Pneumococcal infections. In: Pickering LK, ed. *Red Book: 2012 Report of the Committee on Infectious Diseases*. Elk Grove Village, IL: American Academy of Pediatrics; 2012:571–82.)

Examination of CSF for the presence of bacteria by microscopy and culture yield a bacterial etiology in more than 70% of children that have not as yet received antimicrobial therapy.²¹⁴ Antigen-detection assays, such as latex agglutination and now PCR assays, enhance the identification of bacterial pathogen and are of most value in those children who received antimicrobial treatment before performance of the lumbar puncture.²⁹⁸ PCR assays can also effectively identify pneumococcal serotypes in CSF samples, especially when patients have already been started on antibiotics.⁹²

Prolonged fever, lasting more than 10 days, or recurrence of fever after initial defervescence is reported in pneumococcal meningitis.⁶⁷ Most often, an alternative diagnosis of a nosocomial infection is found in children with recurrent fever. Diagnoses such as viral infection, phlebitis, urinary tract infection (especially in children requiring catheterization) or drug fever are common. Occasionally, complications of pneumococcal infection—such as subdural effusion, complicated pneumonia with effusion, endocarditis, or pericarditis—may be the source.¹²⁹ Relapse of the meningitis has been reported rarely as the cause for prolonged or secondary fever.¹²⁹ The outcome and long-term complications of pneumococcal meningitis include severe hearing loss, seizures, learning or mental difficulties, or paralysis.²⁵ Patients with pneumococcal meningitis have a higher mortality rate and are at greater risk for the development of neurologic sequelae than are patients with *N. meningitidis* or Hib infection.^{289,407} The mortality rate varies from 6.3% to 20%, with the highest mortality in the youngest children.⁴⁹⁴ A peripheral WBC count of less than 5000/mm³ at initial evaluation was recognized as a poor prognostic factor. A high mortality rate and a trend toward a higher mortality rate also was noted if the CSF WBC count was less than 1000/mm³.³¹⁵ A similarly poor outcome can be predicted in patients with pneumococcal meningitis when low CSF glucose concentrations (<1.11 mmol/L)¹⁷⁷ or high CSF protein concentrations (>250 mg/dL) are present.³¹⁵ A multicenter US study reported a 7.7% mortality rate, with 25% of children suffering neurologic morbidities and 32% with moderate or severe hearing loss.²⁵

Children who have cochlear implants are more than 30 times more likely than healthy children to acquire pneumococcal meningitis, presumably from direct extension from the nasopharynx or middle ear. Implants

with positioners were associated with a greater risk than those without. The risk period for development of pneumococcal meningitis appears to extend for 24 months after implantation.^{56,460} Delayed sterilization of CSF cultures after antimicrobial treatment also has been associated with a poorer outcome.³³³

Higher incidence rates, greater case-fatality rates, and more frequent neurologic sequelae have been observed in children from developing countries compared to those from industrialized countries. Case-fatality rates in excess of 50% have been reported from some African and Asian countries, including studies performed during the late 1990s and early 2000s.^{88,418,427,470,486} The case-fatality rates from pneumococcal meningitis in developing countries and indigenous native populations in fact exceed the overall annual incidence rates of pneumococcal meningitis in industrialized countries by 15-fold to 100-fold.⁵²⁴ The in-hospital case-fatality rates provide a minimal estimate as to the true mortality associated with pneumococcal meningitis, as indicated by studies with follow-up beyond the hospitalization period. A study in The Gambia showed that 23% of hospital survivors subsequently died in the community, mainly related to neurologic sequelae resulting from the meningitis.²⁶⁰ Late clinical presentation of cases to the hospital as well as delays in diagnosing meningitis—for example, 22% initial erroneous misdiagnosis of pneumococcal meningitis as malaria in Malawi³⁸⁷—may contribute to this high mortality. The review by Peltola reported that mortality rates for pneumococcal meningitis (45%) were greater than for *H. influenzae* (29%) or *N. meningitidis* (8%).⁴³⁵ A meta-analysis on mortality due to bacterial meningitis in developed countries also found higher mortality rates associated with pneumococcal meningitis (15.3% vs. 3.8% for *H. influenzae* type b and 7.5% for *N. meningitidis*).⁴⁷

Pneumonia

Defining pneumococcal pneumonia in children remains a challenge, as a specific pathogen cannot be documented in most cases unless bacteremia or empyema occur. Vaccine probe studies have helped to redefine the spectrum of clinical pneumonia associated with *S. pneumoniae* and extended the clinical description beyond lobar pneumonia. Lobar pneumonia remains the classical pulmonary disease resulting from pneumococcal infections. High fever exceeding 40°C, general fatigue, a productive cough, and dyspnea are the prototypic presenting signs and symptoms. In older children, chest pain is often associated with a lobar infiltrate. Fever and cough are nearly universal, occurring in 90% and 70%, respectively. Severe abdominal pain is often a presenting symptom in left lower lobe disease; chest pain occurs in 10% to 50% of patients⁵⁴² and meningeal signs may be present with apical infiltrates, especially in young children. Comparison of pneumococcal pneumonia with respiratory syncytial virus demonstrates significant overlap in presentation. Children with pneumococcal pneumonia less often have tachypnea but more often high WBC counts (mean of 20,800/mm³ in pneumococcal pneumonia) and high CRP level (mean of 137 mg/L). Alveolar infiltrates are observed more frequently, but not exclusively, in pneumococcal pneumonia.²⁸⁵ Children with bacteremic pneumococcal pneumonia appeared more ill than children with nonbacteremic pneumococcal pneumonia. Lobar infiltrates on chest radiographs were present in the majority of bacteremic cases. Pleural effusion is common and occurs in up to 40% of patients; however, only 10% have substantial fluid accumulation and 2% develop empyema.³⁴⁵ Patients with pleural fluid secondary to pneumonia have the usual signs and symptoms, with chest pain, abdominal pain, egophony, and/or dullness on percussion. A pleural friction rub, abdominal pain, and dullness on percussion may also be present. Persistent fever, lasting as long as 3 weeks, can be associated with even relatively small effusions.⁵⁴² Several studies have reported *S. pneumoniae* as the most common cause of empyema in children.⁸⁵ It was most commonly reported in children between 3 and 5 years of age. Serotypes 1, 19A, and 3 were the most common pneumococcal serotypes identified in children with empyema.⁸⁴

Establishing the diagnosis of a specific pathogen in children with pneumonia remains challenging. Blood culture is positive in no more than 10% of patients with pneumococcal pneumonia.⁵⁸⁵ Children with bacteremic pneumococcal pneumonia usually have a high temperature and leukocytosis on admission, with peripheral WBC counts exceeding 15,000/mm³, similar to those without bacteremia.⁵⁵⁰ Based

FIG. 85.14 Segmental (round) pneumococcal pneumonia in 28-month-old child. (From American Academy of Pediatrics. Pneumococcal infections. In: Pickering LK, ed. *Red Book: 2012 Report of the Committee on Infectious Diseases*. Elk Grove Village, IL: American Academy of Pediatrics; 2012:571–82.)

on vaccine probe studies, Madhi et al. reported that procalcitonin and CRP were equally useful in children infected and not infected with HIV to improve the specificity of the pneumococcal pneumonia efficacy endpoint in the vaccine trial among children with radiologically confirmed pneumonia.³⁵⁸

No strict radiologic definition of pneumococcal pneumonia in children is accepted broadly. At one end is the typical appearance of severe lobar consolidation (Fig. 85.14), which is recognized as associated with bacterial pneumonia.⁶⁰³ At the other end are the mild interstitial and perihilar changes that are often associated with viral infections or asthma and that may be part of the spectrum of normal appearances for children in developing countries. In studies performing lung aspiration in cases of radiologically proven lobar infiltrates, the proportion of patients in whom *S. pneumoniae* was detected was high.^{161,576,581} *S. pneumoniae* was the predominant bacterial pathogen in most studies of children with lobar infiltrates (Table 85.6).³⁵⁹ The role of the pneumococcus in children with lobar infiltrates is further supported by the observed 63% reduction in pneumonia with alveolar infiltrates in children vaccinated with a PCV-7 compared to children receiving placebo.⁶⁰

While the role of the pneumococcus in children with lobar consolidation is known, its role in cases with other radiologic findings is not as well defined. Studies demonstrating a reduction in hospitalizations associated with viral pneumonia in children immunized with PCV suggests a role for the pneumococcus in disease manifesting as interstitial and perihilar infiltrates, as least in countries such as South Africa. A study found that the incidence of human metapneumovirus lower respiratory tract infection was reduced by 45% and the incidence of clinical pneumonia was reduced by 55% percent in non-HIV-infected children who had received three doses of conjugate pneumococcal vaccine. In fully vaccinated HIV-infected children, the incidence of human metapneumovirus-associated lower respiratory tract infection was reduced by 53% and that of clinical pneumonia by 65%.³⁵⁷

In the preantibiotic era, the natural course of pneumococcal pneumonia consisted of 7 to 9 days of a stationary phase of symptoms followed by worsening of the systemic signs (“precrisis”) and high mortality. Today, the mortality rate in industrialized countries is extremely low—less than 1%—even in cases of bacteremic pneumonia and long-term complications are uncommon.²⁹¹ However, hemolytic uremic

TABLE 85.6 Etiology of Pneumonia Based on Lung Aspirate Studies³⁵⁷

Continent	Age	No.	% Culture Positive	INFECTIOUS AGENT, N (%)

Modified from Madhi S, Pelton SI. Epidemiology, diagnosis and treatment of serious pneumococcal infections in children from pneumococcal vaccines. In: George R. Siber, Keith P. Klugman, P. Helena Makela, eds. *The Impact of Conjugate Vaccine*. Washington, DC: ASM Press; 2008:95–108.

syndrome in association with pneumococcal pneumonia and bacteremia is being reported with increasing frequency. Thirty-seven cases occurring between 1997 and 2009 in North America were reported from the Emerging Infection Network.⁴⁵ In general, the patients were severely ill, presented with pneumonia and bacteremia, and half of the patients required mechanical ventilation and chest tube placement or video-assisted thoracoscopic surgery. Ninety-two percent of cases were associated with PCV13 serotypes, with serotype 19A recovered from half of the children. Twenty cases have been reported from Taiwan.³³⁴

Otitis Media

Between 25% to 60% of cases of AOM are attributable to the pneumococcus. The bacteriologic outcome of *S. pneumoniae* AOM is less favorable than is the outcome of AOM caused by other organisms when untreated or treated inappropriately.^{308,400,421} The pathogenesis is thought to reflect recently acquired colonization in combination with viral respiratory tract infections in most cases.^{308,400} Some studies have suggested that pneumococcal AOM is more severe than that caused by other pathogens; however, the overlap in signs and symptoms prevents clinical criteria alone from accurately predicting the etiologic pathogen. Observations from 1970 support that pneumococcal AOM is accompanied more frequently by greater pain and higher fever than was AOM caused by other pathogens, is more purulent as characterized by higher middle ear fluid WBC counts, and that the tympanic membrane is more erythematous.^{78,251} Subsequent studies have reported that when *S. pneumoniae* is recovered from the nasopharynx at the time that AOM is present, there are greater abnormalities in the tympanic membrane, as reflected in higher severity score and greater likelihood of persistent symptoms on day five, persistence of tympanic membrane abnormalities on day 28, and recurrence before day 28.¹⁶⁰ Spontaneous remission of the infection occurs less commonly in patients with pneumococcal AOM than in those with other pathogens.²⁵⁰ Tympanic membrane perforation is also more commonly observed with pneumococcal otitis.

Mastoiditis

Acute mastoiditis is the most common suppurative complication of AOM.¹¹⁴ *S. pneumoniae* is the most common cause of acute mastoiditis in children and accounts for 25% to 46% of all culture-proven cases.^{198,248} Increased cases of mastoiditis due to multidrug-resistant *S. pneumoniae* have been reported following the introduction of PCV7 in the United States.⁴²² Studies of the incidence of mastoiditis suggest a higher rate of disease in countries in which observation is the first-line approach to children with otitis media; however, the risk still remains remarkably small in such countries.⁵⁶⁵

Sinusitis

Studies suggest that 5% to 10% of all upper respiratory tract infections are complicated by bacterial sinusitis when defined as either acute, febrile illness with facial swelling (usually localized to the eye), initial improvement in upper respiratory tract infection signs and symptoms, and then recurrence of signs and symptoms or persistence of rhinorrhea,

low-grade fever, facial swelling without improvement beyond 10 days.⁵⁷⁹ *S. pneumoniae* is the pathogen most commonly isolated from patients with sinusitis, and it causes 35% to 42% of all bacterial cases.⁵⁸⁰

Conjunctivitis

Purulent bacterial conjunctivitis due to *S. pneumoniae* is well described, with nonencapsulated strains most often involved. Clinically, bilateral, purulent discharge is the most common clinical presentation and often distinguishes it from viral disease.^{62,194,578,591} When conjunctivitis is present with AOM, the so-called “conjunctivitis-otitis” syndrome, *H. influenzae* is the most common pathogen.⁶⁴

A study in Minnesota⁵⁵¹ evaluated children with conjunctivitis in two cities. A total of 49% of positive cultures were *S. pneumoniae*. All isolates were nontypeable. Pulsed-field gel electrophoresis identified three clonal groups, with 84% of the isolates belonging to one clonal group. Multilocus sequence typing revealed that isolates had the same multilocus sequence type as that of isolates from a 2002 pneumococcal disease outbreak at a New England college. It has been suggested that certain pneumococcal strains have a predilection for causing conjunctivitis.⁸³ These reports suggest that pneumococcal conjunctivitis can be highly contagious in school settings.

Bone and Joint Infections

Septic arthritis caused by *S. pneumoniae* is a relatively rare condition that accounts for 2.2% to 9.7% of all cases.^{219,482} Its main initial clinical features are single or multiple swollen, warm, and painful joints. The joints most commonly involved are the knee and the ankle.²⁶² In one study, the mean duration of symptoms before hospitalization was 2 days, and patients were hospitalized for an average of 11 days. The mean peripheral WBC count was 20,600/mm³, the erythrocyte sedimentation rate usually was greater than 90 mm/h, and the CRP concentration generally was higher than 100 mg/L. *S. pneumoniae* can be isolated from synovial fluid or blood in most patients.⁴⁸² The outcome is favorable in the majority of cases unless underlying diseases or sepsis occurs concomitantly.²⁶²

Soft Tissue Infections

S. pneumoniae has become an uncommonly recognized etiologic agent of soft tissue infections but can cause serious infections. Most commonly, facial cellulitis has been described in otherwise healthy children in conjunction with recovery of *S. pneumoniae* from either local or systemic cultures.¹⁴¹ Periorbital infection can be a complication of sinus disease and can uncommonly spread to the orbit, resulting in orbital cellulitis or abscess manifested as proptosis and ophthalmoplegia.⁵⁰⁴ Most patients with such complications are younger than 3 years of age and previously were healthy. Fever and peripheral WBC counts higher than 15,000/mm³ can be observed in most patients, and blood cultures frequently are positive. Overall, response to therapy generally is good, and patients usually recover.¹⁹⁹ In patients with connective tissue diseases, such as systemic lupus erythematosus and HIV infection, or undergoing corticosteroid treatment, pneumococcal cellulitis has been reported and may be severe.

Peritonitis

Primary peritonitis, in which the pathogen travels from the blood or via the lymphatic system to the peritoneal cavity, is an uncommon condition that accounts for only 17% of all cases of peritonitis. *S. pneumoniae* is the major pathogen in primary peritonitis, responsible for 38% of all cases.²⁰⁴ Primary pneumococcal peritonitis should be considered in the differential diagnosis of children with an acute abdominal syndrome,¹⁸¹ particularly in children with nephrotic syndrome, immunocompromised status, or sickle-cell disease.²⁰⁴ Colonization of the perineum and subsequent spread via the fallopian tube to the peritoneal cavity has been suggested as the pathogenesis of primary pneumococcal peritonitis and is consistent with the observation that 87% of cases occur in females.^{501,514} Most of the patients are between 4 and 10 years of age.⁵⁰¹ Symptoms include diffuse abdominal pain, fever, vomiting, and diarrhea. Abdominal tenderness can be maximal in the right lower quadrant, which can lead to confusing it with acute appendicitis. In some cases, *S. pneumoniae* can be isolated as the only cause of peritonitis secondary to appendicitis. Cultures should include blood, peritoneal fluid, and a vaginal swab. Some patients need laparotomy or laparoscopy to exclude other pathologies, such as appendicitis or a tubo-ovarian abscess.⁵¹⁴ Morbidity and mortality rates can be high when the period without treatment exceeds 1 week, but in most cases, the outcome is favorable when treated adequately.⁵⁰¹

Endocarditis

S. pneumoniae endocarditis is most often reported to involve the aortic and mitral valves. The syndrome of pneumococcal meningitis, pneumonia, and endocarditis was previously more common. It was initially described by Osler but is also known as Austrian syndrome. This triad is now uncommon and *S. pneumoniae* currently accounts for less than 3% of cases of bacterial endocarditis.^{263,396,543} This triad is rarely present in children. In children, mitral valve involvement has been described most frequently. A history of congenital heart disease is often present. Medical therapy alone has a high mortality rate that was improved in a group of patients receiving combined medical and surgical interventions.⁹⁸

Pericarditis

In the preantibiotic era, pneumococcal pericarditis was a relatively frequent complication of lobar pneumococcal pneumonia and the most common pathogen in purulent pericarditis in children. After the introduction of antibiotics, the pneumococcus declined as a cause of pericarditis, decreasing from 51% to 9% of cases and occurring mainly in adults. Currently, infections of the pericardium are rare in children and often are related to underlying medical conditions, such as immunodeficiency.⁴³⁶

Infection in Immunocompromised Hosts

Patients with functional asplenia, including those with hemoglobinopathies, are at high risk for invasive pneumococcal disease. In 19 asplenic patients with invasive pneumococcal infection, the clinical findings included fever (86%), shock (27%), petechiae or purpura (27%), disseminated intravascular coagulopathy (18%), and respiratory distress (18%). Clinical illness included bacteremia alone (52%), meningitis (26%), bacteremia with otitis/sinusitis (13%), and bacteremia with pneumonia (9%). The mortality rate was 32%.⁴⁹⁶

HIV-infected children with pneumonia usually have the typical symptoms of fever, shortness of breath, and productive cough associated with pleuritic pain. The chest radiograph shows unilobar or multilobar infiltrates, and peripheral WBC counts often are elevated. A comparison between HIV-infected and non-HIV-infected children with CAP showed no significant differences between groups with regard to the duration of hospitalization and mortality rates.³⁶¹ In contrast, when only patients infected with isolates belonging to the traditional “pediatric serotypes” (see the sections on [epidemiology](#) and [prevention](#)) were compared, a higher rate of pneumonia with or without concurrent meningitis in the HIV-infected group was observed. Recurrence of pneumococcal infection within 6 months from the initial episode is also common in patients infected with HIV, particularly children.¹⁸⁸ Most HIV-infected patients recover without significant sequelae, and the clinical course of

their systemic infection does not appear to be markedly different from that in healthy children.²⁷⁵

Patients with immunodeficiency disorders consisting of antibody and complement deficiencies are at high risk for acquisition of invasive and recurrent pneumococcal infection.²⁷⁵ Children with nephrotic syndrome have a particularly increased risk for the development of pneumococcal peritonitis, mainly during relapse of their renal disease.¹⁶⁵ Children with sickle-cell disease are prone to the development of overwhelming *S. pneumoniae* bacteremia and sepsis; in children younger than 3 years of age, the incidence of bacteremia is 6.1 events per 100 patient-years, and the case-fatality rate is 24% for *S. pneumoniae* sepsis.⁶¹⁶

S. pneumoniae is an important pathogen in patients undergoing bone marrow transplantation (BMT) or peripheral blood stem cell transplantation with two patterns of disease recognized. Early onset is observed in both allogeneic and autologous BMT and peripheral blood stem cell transplantation patients within the first 35 days. Later-onset disease occurs after 100 days and is more frequent in allogeneic compared to autologous BMT and is the most common bacterial infection in such patients. Functional hyposplenism secondary to irradiation, chronic graft versus host disease, and decreased IgG2 antibody contribute to the risk of invasive pneumococcal disease and the poor outcome. Case-fatality rates approximate 20%.³²² Chronic graft versus host disease is associated with long-term risk for pneumococcal infections in recipients of BMTs.^{155,322}

Solid-organ transplant patients are at increased risk of pneumococcal disease. The risk varies with the nature of the transplant. However, recipients have a lifelong increase in risk due to the immunosuppressive therapy required for transplant survival and recurrent disease is common. Of 42 children who had undergone BMT or solid-organ transplantation and became infected with *S. pneumoniae*, 8 (19%) had recurrent pneumococcal infections.⁴⁹⁷ Solid-organ recipients were more likely to have recurrent invasive disease than were recipients of BMTs. Death occurred in 2 of 42 recipients (5%). Cardiac transplant patients have an incidence of 39 cases of invasive pneumococcal infection per 1000 patients per year,⁵²⁷ the highest risk of which occurs in African American heart transplant recipients who undergo transplantation because of idiopathic dilated cardiomyopathy.

TREATMENT

The pneumococcus is the causative bacterial agent in many respiratory and invasive infections, many of which are often treated empirically. Empiric and pathogen-directed treatment guidelines are available for the major disease syndromes associated with pneumococcal infection. In the absence of rapid methods for diagnosis of disease and identification of drug-resistant strains, empiric treatment will continue to be the rule in clinical practice.

Dosing regimens and susceptibility of β -lactam and non- β -lactam antimicrobial agents used to treat pneumococcal infections are shown in [Tables 85.7](#) and [85.8](#), respectively.²⁶⁷ Dosing regimens are shown as total recommended daily dose and number of doses per day and should be used in conjunction with local prescribing information. Susceptibility data reflect overall findings from US and international studies; local susceptibility data should be taken into consideration as susceptibility patterns may vary considerably.

Pneumonia

Guidelines for the management of infants and children older than 3 months of age with presumed bacterial CAP have been published by the Pediatric Infectious Diseases Society and the Infectious Diseases Society of America.⁷¹ Children with mild disease severity should be considered for outpatient treatment with antibiotics; amoxicillin should be used as first-line therapy for previously healthy, appropriately immunized infants and preschool children with mild to moderate CAP. In children allergic to amoxicillin, second- or third-generation cephalosporins, oral levofloxacin, or oral linezolid may be appropriate. For children who do not have clinical, laboratory, or radiographic evidence that distinguishes bacterial from atypical pneumonia, a macrolide can be added to the β -lactam antibiotic, especially in school-aged children and adolescents. Hospitalization is required for any child requiring

TABLE 85.7 Dosing Regimens and Susceptibility of β -Lactam Antimicrobial Agents Used to Treat Pneumococcal Infections

Antimicrobial Agent	TOTAL DAILY DOSE (NO. OF DOSES/DAY)		Susceptible Breakpoint (µg/mL) ^a	% Susceptibility
	Adolescents	Infants and Children		
Parenteral Agents—Meningitis				
Penicillin G	24 million units (6–8)	300,000–400,000 units/kg (4–6)	≤0.06	63.5
Ampicillin	12 g (6)	300 mg/kg (4)	Penicillin ≤0.06	68.3
Ceftriaxone	4 g (1–2)	100 mg/kg (1–2)	≤0.5	82.2–86.2
Cefotaxime	8–12 g (4–6)	225–300 mg/kg (4–6)	≤0.5	87.4
Cefepime	6 g (3)	150 mg/kg (3)	≤0.5	85.3
Meropenem	6 g (3)	120 mg/kg (3)	≤0.25	78.1–93.9
Parenteral Agents—Nonmeningeal Infections				
Penicillin G (regular dose)	12 million units (6)	250,000–400,000 units/kg (4–6)	≤ ^b	92.6
Penicillin G (high dose)	18–24 million units (6)	400,000 units/kg (4–6)	≤4	99.7 ^c
Ampicillin	4–8 g (4)	50–100 mg/kg (4)	Penicillin ≤2	92.6
Ceftriaxone	1-2 g (1)	50–75 mg/kg (1-2)	≤1	95.2
Cefotaxime	3 g (3)	75–100 mg/kg (3–4)	≤1	95.1–96.5
Cefuroxime sodium	2.25 g (3)	50–100 mg/kg (3–4)	≤0.5	75.3
Cefepime	2 g (2)	100 mg/kg (2)	≤1	96.5
Ceftaroline	1.2 g (2)	NA	≤0.25	100
Meropenem	1.5–3 g (3)	60–120 mg/kg (3)	≤0.25	78.1–93.9
Imipenem	1–2 g (3–4)	60 mg/kg (4)	≤0.12	92.4–96.3
Ertapenem	1 g (1)	30 mg/kg (2)	≤1	93.2–93.3
Oral Agents				
Penicillin V	1–2 g (3–4)	25–50 mg/kg (3-4)	≤0.06 ^b	63.5
Amoxicillin (regular dose)	1.5 g (2–3)	45 mg/kg (2–3)	≤2	84–92.2
Amoxicillin/clavulanate (regular dose)	1.5 g/250 mg (2–3)	45/6.4 mg/kg (2–3)	≤2	84–93.6
Amoxicillin (high dose)	6 (3)	90 mg/kg (2–3)	≤4	86–92.2
Amoxicillin/clavulanate (high dose and extended release)	4 g/250 mg extended release (2)	90/6.4 mg/kg (2–3)	≤4	86–93.6
Cefaclor	750–1,500 mg (3)	20–40 mg/kg (3)	≤0.5	60.2
Cefuroxime axetil	500–1,000 mg (2)	20–30 mg/kg (2)	≤1	68–78.2
Cefixime	400 mg (1–2)	8 mg/kg (1–2)	≤1	68.3
Cefprozil	500–1,000 mg (2)	15–30 mg/kg (2)	≤1	79.7
Cefdinir	600 mg (1–2)	14 mg/kg (1–2)	≤0.5	68–76.8

Modified from Jacobs MR. Antimicrobial-resistant *Streptococcus pneumoniae*: trends and management. *Expert Rev Anti Infect Ther*. 2008;6(5):619-35.

Dosing regimens are shown as total recommended daily dose and number of doses per day and should be used in conjunction with local prescribing information. Susceptibility data reflect overall findings from US and international studies, and local susceptibility data should be taken into consideration, as susceptibility patterns may vary considerably.

^aSusceptibility breakpoint for agent shown unless specified otherwise.

^bNonmeningeal isolates susceptible to penicillin G at this breakpoint can be considered susceptible to parenteral ampicillin, cefepime, cefotaxime, and ceftriaxone. Nonmeningeal isolates susceptible to $\leq 0.06 \mu\text{g/mL}$ of penicillin G can be also considered susceptible to these parenteral agents as well as to parenteral ertapenem, imipenem, and meropenem and to oral ampicillin, amoxicillin, amoxicillin/clavulanate, cefaclor, cefdinir, cefditoren, cefprozil, cefuroxime, and cefpodoxime.

^cIncludes penicillin G susceptible (92.6%) and intermediate (7.1%) isolates based on new, nonmeningeal, parenteral penicillin G susceptibility breakpoints.

NA, Not available.

intravenous therapy, hydration, or respiratory support. For inpatient treatment of children fully immunized with conjugate pneumococcal and *H. influenzae* type b vaccines, parenteral ampicillin, penicillin G, ceftriaxone, or cefotaxime are recommended, with the addition of clindamycin or vancomycin if community-acquired methicillin-resistant *S. aureus* is suspected. Except for ampicillin and penicillin G, the same agents are recommended for children who are not fully immunized. If atypical pneumonia cannot be excluded from the differential diagnosis, addition of azithromycin is recommended, with doxycycline and levofloxacin alternatives for older children. Other agents approved for treatment of pneumococcal pneumonia in adults include linezolid, tigecycline, and ceftaroline, a cephalosporin with anti-methicillin-resistant *S. aureus* activity.²⁷⁹ Recently, the US Food and Drug Administration added a black box warning for quinolones (levofloxacin included) that such antibiotics may cause potentially permanent damage to muscles, tendons, joints, nerves, and the central nervous system and should not be used in patients with “minor” infections.¹⁷⁶ While bacterial pneumonia

is not included in the Food and Drug Administration categorization of minor infections and the linkage between permanent damage and quinolones is primarily associative, caution should be used in prescribing levofloxacin in children for cases of pneumonia in which the likelihood of bacterial disease is small.

Sinusitis

While fewer than 2% of cases of acute viral rhinitis are complicated by acute bacterial rhinosinusitis, patients with symptoms lasting more than a week or increasing in severity after 5 to 7 days can be indicative of bacterial superinfection requiring treatment with antimicrobial agents. Detailed recommendations for treatment of acute bacterial sinusitis are found in Chapter 14.

Acute Otitis Media

AOM is the most commonly treated bacterial infection in children. Current guidelines for treatment are discussed in details in Chapter 16.

TABLE 85.8 Dosing Regimens And Susceptibility of Antimicrobial Agents Other Than β -Lactams Used to Treat Pneumococcal Infections

	TOTAL DAILY DOSE (NUMBER OF DOSES PER DAY)		Susceptible Breakpoint (μg/mL) ^a	Percent Susceptibility
Antimicrobial Agent	Adolescents	Infants and Children		
Parenteral Agents—Meningitis				
Vancomycin	30–60 mg/kg (3–4)	60 mg/kg (4)	≤1	100
Rifampin	600 mg (1)	20 mg (1–2)	≤1	99.9
Chloramphenicol	4–6 g (4)	75–100 mg/kg (4)	≤4	88.1
Parenteral Agents—Nonmeningeal Infections				
Vancomycin	2 g (2–4)	40–45 mg/kg (3–4)	≤1	100
Oral Agents				
Doxycycline	200 mg day 1, then 100 mg (1)	NR	≤0.25	71.3
Co-trimoxazole	320/1600 mg (2)	8/40 mg/kg (2)	≤0.5/9.5	56–69.0
Oral and Parenteral Agents				
Levofloxacin	500–750 (1)	NR	≤2	99.2
Gemifloxacin	320 (1)	NR	≤0.25	99.9
Moxifloxacin	400 (1)	NR	≤1	99.6
Erythromycin	1–2 g (4)	30–50 mg/kg (4)	≤0.25	70.9
Clarithromycin	500–750 mg (1–2)	15 mg/kg (2)	≤0.25	71.1
Azithromycin	500 mg day 1, then 250–500 mg (1)	10 mg/kg day 1, then 5–10 mg/kg (1)	≤0.12	55–65.5
Clindamycin	600–1200 mg (4)	16–40 mg/kg (4)	≤0.25	66.7
Linezolid	1200 mg (2)	30 mg/kg (3)	≤2	100

Modified from Jacobs MR. Antimicrobial-resistant *Streptococcus pneumoniae*: trends and management. *Expert Rev Anti Infect Ther*. 2008;6(5):619-35.

Dosing regimens are shown as total recommended daily dose and number of doses per day and should be used in conjunction with local prescribing information. Susceptibility data reflect overall findings from US and international studies; local susceptibility data should be taken into consideration as susceptibility patterns may vary considerably.

^aSusceptibility breakpoint for agent shown unless specified otherwise.

NR, Not recommended for use in infants and children.

Bacteremia

S. pneumoniae is a common cause of bacteremia in children, frequently associated with pneumonia, and treatment guidelines follow recommendations for treatment of pneumonia.^{99,267}

Meningitis

After PCV7 introduction, an estimated 3330 pneumococcal meningitis hospitalizations and 394 deaths were prevented in persons of all ages during 2001 to 2004 in the United States, and pneumococcal meningitis is now more common in adults than in children.⁵⁵⁵ The Infectious Diseases Society of America has published practice guidelines for the management of bacterial meningitis.²²⁴ Detailed treatment strategies are discussed in Chapter 31.

PREVENTION

Nonimmunologic Strategies

This category includes interventions that aim at (1) reducing risk factors predisposing to the development of pneumococcal infection, (2) providing antimicrobial prophylaxis to abort or prevent pneumococcal colonization or disease, and (3) modifying anatomic abnormalities that predispose to the development of pneumococcal infection.³⁰⁹

A factor that is important not only for pneumococcal infection but also for many other serious bacterial infections is the need to improve general health and nutrition worldwide, particularly in low-income countries. Many risk factors for the acquisition of pneumococcal infection that can be alleviated include poor living conditions, overcrowding, poor hygiene, malnutrition, and a high prevalence of viral infections, particularly respiratory viruses, measles, and HIV. In high-income countries, carriage of pneumococci, especially antibiotic-resistant strains that result in sporadic infections and outbreaks, is related to daycare attendance and is proportional to the number of children per group.^{96,105,120,122,340,458,538} Therefore, reducing the number of children per group in daycare centers and developing alternative forms of childcare may reduce the rate of pneumococcal morbidity.

The importance of passive smoking (namely, being in close contact with smokers in the same household) has been highlighted as a risk

factor for the development of pneumococcal disease.⁴¹² Thus, efforts to prevent smoking in the home may have an important role in the prevention of pneumococcal infection. Breastfeeding may protect against some infections related to *S. pneumoniae*, such as otitis media.^{19,81,147,475,559} Therefore, breastfeeding should be encouraged, especially in families in which otitis media occurs commonly, although the precise role of prolonged breastfeeding in protecting against pneumococcal infection has not been established.

Antimicrobial chemoprophylaxis is used predominantly for two indications: prevention of recurrent AOM and prevention of pneumococcal sepsis in children with anatomic or functional asplenia. Data now exist to support the common practice of prescribing regular doses of penicillin for children with asplenia or sickle-cell disease.¹⁸⁶

The potential benefits of otitis media chemoprophylaxis have been weighed against the ability of chemoprophylaxis to alter the nasopharyngeal flora, foster colonization with resistant organisms, and thereby compromise the long-term efficacy of the prophylactic drug and contribute to the propagation of resistant organisms throughout the community. As a result, the practice of otitis media chemoprophylaxis has been reduced greatly. In one study, prophylaxis with amoxicillin induced a dramatic increase in the carriage of penicillin-resistant *S. pneumoniae* and increased carriage of other resistant pathogens.⁷⁹ The fear of increasing resistance led the Committee on Infectious Diseases of the American Academy of Pediatrics to issue a warning against the widespread use of otitis media prophylaxis and to state that “Antimicrobial prophylaxis should be reserved for control of recurrent acute otitis media, defined by 3 or more distinct and well-documented episodes during a period of 6 months or 4 or more episodes during a period of 12 months.” Surgical otitis media prophylaxis by insertion of tympanostomy tubes or adenoidectomy (with or without tonsillectomy) has been recommended for otitis-prone children³⁰⁷ (see Chapter 16).

Immunoprophylaxis

Unconjugated Capsular Polysaccharide Vaccines

It is well established that both passive immunization by administration of specific antibodies and active immunization with polysaccharides can provide protection against many pneumococcal infections.

Passively administered serotype-specific antibodies can protect animals and humans against diseases caused by pneumococci, with administration of antisera associated with improved clinical outcome, including reduced mortality, in humans.⁸⁹ Human immunoglobulins can prevent experimental pneumococcal bacteremia in mice^{101,480} and otitis media in chinchillas.⁵⁰⁷ The finding of low cord blood IgG antibodies, mainly of the IgG1 subset, is predictive of early-onset AOM in infancy.^{49,349,487} In several clinical studies, bacterial polysaccharide immune globulin obtained by immunizing healthy adults with a 14-valent pneumococcal vaccine (in addition to group C meningococcal and Hib polysaccharide vaccines) decreased the prevalence of AOM⁵⁰⁹ and invasive infection⁵⁰⁹ in children.

Immunization with pneumococcal polysaccharide antigens, mainly in adults, has been studied for a long time. First, hexavalent polysaccharide vaccines were introduced in the late 1940s, followed by 14-valent vaccines in the late 1970s and 23-valent vaccines in the early 1980s. The last, produced by several manufacturers, contains 25 µg of purified, non-conjugated polysaccharide antigens per dose for serotypes 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F. These 23 serotypes accounted for approximately 90% of the serotypes responsible for invasive pneumococcal infection in all age groups in both developed and developing countries.^{230,231,467,520} The 23-valent polysaccharide vaccines are tolerated well by healthy children for primary^{335,500} or repeated immunization.⁶⁹ However, the presence of preexisting antibodies was associated with an increased incidence of adverse events at the site of injection.^{63,317,415}

Generally speaking, these bacterial polysaccharide-based vaccines are poorly immunogenic in infants and toddlers for important disease-causing serotypes, which is to be expected because bacterial capsular polysaccharides induce antibody production primarily by T-cell-independent mechanisms that still are not fully developed in this age group.⁴⁶³ Polysaccharide-specific IgG concentrations are relatively high in very young infants because they are acquired transplacentally and consist mainly of IgG1. Nasopharyngeal colonization with various serotypes of *S. pneumoniae* results in the natural production of serotype-specific antibodies.^{82,235,549,600} The immune response to pneumococcal polysaccharides is serotype dependent, and some serotypes commonly associated with disease are especially poor immunogens until children reach the age of approximately 5 years.¹⁴⁵ Serotypes 6A, 6B, 12, 19A, 19F, and 23F are examples of this phenomenon.^{121,145,316,335,338,521,549,600} The IgG subclasses that are produced after exposure to polysaccharide antigens of other bacterial species are mainly IgG2 and IgG4.³⁴⁶ A second dose of polysaccharide vaccine does not provide a booster effect and even may result in a reduced immune response when compared with the response after the first dose, which may suggest antigenic tolerance.^{63,413,570} Children with many underlying conditions that predispose to the development of pneumococcal infection often respond more poorly to pneumococcal polysaccharide vaccines than do otherwise normal children. Published studies of children with recurrent respiratory tract infections all have demonstrated this phenomenon.*

In addition to a relatively poor systemic immune response, the polysaccharide vaccines have been shown to induce only minimal mucosal immune responses. Serotype-specific antibodies to pneumococcal serotypes 6A, 14, 18C, and 23F were measured in the sera and middle ear effusions of 14 children who had received a 14-valent pneumococcal capsular polysaccharide vaccine and in controls.³¹⁶ Serotype-specific antibody concentrations in middle ear effusions correlated with serum concentrations and generally were higher in pneumococcal vaccine recipients than in control vaccine recipients. IgM class antibodies frequently were seen only in the serum samples, thus suggesting that antibodies diffuse into the middle ear space rather than being synthesized in situ in response to the vaccine. This finding refutes previous theories that local production of antibodies occurs in the middle ear after vaccination.^{318,515,516}

Limited data exist regarding the efficacy of polysaccharide pneumococcal vaccines in preventing disease in infants and children. A large study conducted in Papua New Guinea on more than 7000 children

showed a reduction in mortality rates from acute lower respiratory tract disease.^{336,465,464} In this study, the effect was dramatic: a 59% reduction in mortality rates in all children vaccinated (5 months to 5 years of age) and a 50% reduction in children vaccinated before they reached 2 years of age. However, the vaccine did not protect against nonfatal disease. In the United States, researchers have suggested that the polysaccharide vaccines would be 62% effective in preventing invasive pneumococcal disease caused by vaccine serotypes in children aged 2 to 5 years.¹⁷⁰

The effectiveness of polysaccharide pneumococcal vaccines in preventing otitis media is not clear. Several studies have shown some reduction in the incidence of otitis media in vaccinated children.^{144,253,292,365,544} No effect of the use of polysaccharide pneumococcal vaccine on pneumococcal nasopharyngeal carriage could be demonstrated.^{117,121} These studies on T-cell-independent polysaccharide pneumococcal vaccines clearly show that their benefit in children is at best limited to the minority of serotypes that are immunogenic in this age group.

Recent meta-analyses have examined the effect of PPV23 on invasive pneumococcal disease and pneumococcal pneumonia in adults.^{137,320} One concluded that PPV23 provided significant protection against IPD (~50% efficacy) in adults greater than 50 years of age with lower efficacy against CAP (4–17%), dependent on study design. The second reported that PPV23 provided weak protection against all-cause pneumonia in immunocompetent adults and, although a trend toward protection against pneumococcal pneumonia was present, it was not statistically significant.

Conjugated Capsular Polysaccharide Vaccines

The conjugation of pneumococcal polysaccharides to protein alters the immune response by recruiting T-cells that both amplify the B-cell response and create memory B-cells in contrast to the T-cell-independent nature of the immune response that occurs after the administration of bacterial polysaccharides.^{34,150,296,468,508,525} (Fig. 85.15). These polysaccharide-protein antigens elicit protective antibody in infants and prime the immune system for future boosting with reexposure to the polysaccharide either alone or conjugated. Antibodies elicited by polysaccharide-protein conjugates demonstrate improved functional capacity (determined by avidity and opsonization assays), persist, and result in a booster response with reexposure.¹⁵⁸ The concept of conjugation technology, highly successful with capsular polysaccharide from *H. influenzae* type b, was modified to permit development of vaccines with multiple polysaccharide while maintaining immunogenicity for each individual polysaccharide.

FIG. 85.15 (A) T-cell-independent and (B) T-cell-dependent antibody responses to polysaccharide or polysaccharide-protein conjugate antigens. (From Eskola J, Anttila M. Pneumococcal conjugate vaccines. *Pediatr Infect Dis J.* 1999;18:543–51.)

TABLE 85.9 Pneumococcal Conjugate Vaccines Licensed in at Least One Country or Being Tested in Clinical Trials

Vaccine	Valency	Pneumococcal Polysaccharides	Carrier Protein	Current Status	Manufacturer
PnOMP7	7-valent	4, 6B, 9V, 14, 18C, 19F, 23F	Meningococcal outer-membrane protein complex	Research formulation only	Merck Research Laboratories
PnCRM7	7-valent	4, 6B, 9V, 14, 18C, 19F, 23F	CRM ₁₉₇ protein	Licensed	Pfizer
PnCRM9	9-valent	1, 4, 5, 6B, 9V, 14, 18C, 19F, 23F	CRM ₁₉₇ protein	Research formulation only	Pfizer
PHiD-CV	10-valent	1,4,5,6B,7F,9V,14,18C,19F,23F		Licensed	GlaxoSmithKline
PnC/T/D	11-valent	1, 3, 4, 5, 6B, 7F, 9V, 14, 18C, 19F, 23F	A mixture of tetanus and diphtheria toxoids	Not in commercial development	Aventis Pasteur
Pn-PD	11-valent	1, 3, 4, 5, 6B, 7F, 9V, 14, 18C, 19F, 23F	<i>Haemophilus influenzae</i> —protein D	Prototype for PHiD-CV; not in commercial development	GlaxoSmithKline
PnCRM13	13-valent	1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, 23F	CRM ₁₉₇ protein	Licensed	Pfizer
PCV 15	15-valent	1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, 22F, 23F, 33F	CRM ₁₉₇ protein	In clinical trials	Merck

Currently, vaccines with 7 to 13 different conjugated pneumococcal polysaccharide antigens are licensed and next-generation vaccines with even greater numbers of polysaccharides are in clinical trials.³²⁴

Table 85.9 shows pneumococcal conjugate vaccines that are licensed in at least one country, are being tested in phase III efficacy studies, or are in advanced phase II (safety and immunology) stages. The selection of serotypes for inclusion in the various formulations is based on serotype epidemiology discussed earlier. These conjugate vaccines were developed primarily targeting serotypes responsible for invasive pneumococcal disease, including meningitis, bacteremic pneumonia, and empyema.

The primary target population for polysaccharide conjugate vaccines is infants and toddlers, as disease incidence is highest, global mortality substantial, and polysaccharide vaccines demonstrated to be poorly immunogenic and of limited value at this age. Pneumococcal conjugate vaccines are immunogenic, safe, and well tolerated, with vaccine reactions primarily being pain, redness, and swelling at the injection site. The incidence of fever and irritability was somewhat higher than reported in studies with Hib conjugate vaccines or hepatitis B vaccines, perhaps because the pneumococcal vaccines represent 7 to 13 separate monovalent vaccines administered together as opposed to the monovalent Hib conjugate vaccine or hepatitis B vaccine. The 7-valent pneumococcal vaccine conjugated to CRM₁₉₇ protein (PnCRM7) was found to be safe even when administered to low-birth-weight and preterm infants.³⁰⁵

PCV formulations were demonstrated to elicit high concentrations of IgG1 subclass antibodies, functional antibody in opsonophagocytic assays, and antibody with high avidity.^{158,164} The immunogenicity of one formulation (PnCRM7) was demonstrated to be immunogenic in children with sickle-cell disease,^{410,415,570} HIV infection,^{6,305,306,405} solid-organ transplants,³⁴⁷ allogeneic and autologous bone marrow transplants,^{20,155} as well as in Alaska Natives and American Indians.³⁷⁹ A 9-valent CRM (PnCRM9) pneumococcal vaccine also was immunogenic in children with sickle-cell disease.²⁰¹

Clinical trials were used to evaluate the efficacy of the various pneumococcal conjugate vaccine formulations across a spectrum of endpoints and populations. The endpoints thought to be of most importance in evaluating these vaccines have been (1) prevention of invasive pneumococcal disease as defined by isolation of pneumococci from a normally sterile site (e.g., from blood, CSF, aspirates, and biopsies); (2) prevention of mucosal infections such as otitis media, sinusitis, and nonbacteremic pneumonia; and (3) reduction of nasopharyngeal colonization, which, in turn, results in herd immunity due to reduced transmission of organisms.

Three efficacy studies of conjugate vaccines with the endpoint of a reduction in the number of invasive infections were completed by mid-2002, two with PnCRM7 and one with the PnCRM9 vaccine. The

first study was a prospective double-blind study of 37,868 healthy infants in northern California to whom either the PnCRM7 vaccine or a control vaccine was administered at 2, 4, 6, and 12 to 15 months of age.⁵⁹ The vaccine was 97.4% efficacious (95% confidence interval [CI], 82.7–99.9%) against invasive disease caused by the 7 serotypes included in the vaccine in fully vaccinated infants and 93.9% efficacious (95% CI, 79.6–98.5%) in partially vaccinated infants. No evidence of an increase in invasive disease caused by serotypes that were not included in the vaccine was detected; thus, the overall effect was a reduction in total invasive pneumococcal disease by 89.1% (95% CI, 73.7–95.8%). This trial led to US licensure of the vaccine in February 2000, with subsequent licensure in many other countries. Additional analysis has shown that the vaccine was as effective in the subset of low-birth-weight and premature infants as it was in the full study cohort.⁵⁰⁵ Secondary analyses demonstrated reductions in all-cause pneumonia and AOM.

A second large-scale efficacy study with the PnCRM7 vaccine was conducted among American Navajo and White Mountain Apache children in the United States using a cluster randomization strategy in which communities rather than individuals are randomized. This population has rates of invasive pneumococcal infection that are approximately five times those of the general US population.⁴¹⁴ In this double-blind, community-randomized study, infants and young children aged 2 months to 2 years received the PnCRM7 vaccine or a control vaccine. A total of 8292 infants from 43 communities were enrolled; of these, 8091 lived in 38 communities that were randomized to the pneumococcal or the control vaccine. During the study period, two cases of invasive pneumococcal infection caused by the serotypes included in the vaccine occurred in the vaccine group versus eight in the control group. After controlling for community randomization, the primary efficacy of the vaccine was 76.8% (95% CI, 9.4–95.1%) and the intent-to-treat efficacy was 86.4% (95% CI, 11–96.1%).

A third efficacy study was conducted with the PnCRM9 vaccine among black infants in South Africa. In this double-blind, randomized, placebo-controlled study, PnCRM9 was administered to children at the ages of 6, 10, and 14 weeks according to the World Health Organization's Expanded Programme on Immunization. The infants were monitored until they reached 2 years of age. The intent-to-treat analysis showed a reduction of 82.5% (95% CI, 39.0–96.7%) in the number of invasive infections caused by the serotypes included in the vaccine for children not infected with HIV and a reduction of 65.4% (95% CI, 23.8–85.7%) in antiretroviral-naïve children infected with HIV.³¹³

Once licensed in the United States (February 2000), universal immunization for children less than 2 years of age and selected immunization for high-risk children was implemented in the United States. The Committee on Infectious Diseases of the American Academy of Pediatrics

recommended routine administration as a four-dose series for infants at ages 2, 4, 6, and 12 to 15 months (known as the 3+1 schedule); catch-up immunization was recommended for all children up to 23 months of age. Infants of very low birthweight could be immunized when they reached a chronologic age of 6 to 8 weeks, regardless of their calculated gestational age. The PCV-7 vaccine also was recommended for all children younger than 60 months of age at high risk of acquiring invasive pneumococcal infection, including patients with sickle-cell disease, asplenia, HIV/acquired immunodeficiency syndrome, diabetes, cancer, liver disorders, lung diseases, and cardiac diseases. For some high-risk children, administration of PPV23 was recommended for supplemental protection.

The incidence of invasive pneumococcal disease decreased sharply in infants and toddlers following the widespread use of PCV7 in US children.^{58,254,595} Effectiveness studies demonstrated a rapid decline in IPD due to vaccine serotypes in children less than 5 years of age (Fig. 85.16) within 2 years of vaccine introduction, with a further gradual decline that persisted through 2010, when a second-generation pneumococcal conjugate vaccine was introduced (PCV13).^{441,612} Rates of bacteremia without a focus, meningitis, and bacteremic pneumonia all declined. By 2006 to 2007, PCV7 serotypes accounted for only 2% of IPD cases in children compared to 83% prior to 2000. By 2009, nasopharyngeal PCV7 serotypes comprised only 2% of pneumococcal isolates carried in the nasopharynx of children less than 6 years of age⁶⁰⁶ (Fig. 85.17). Despite the decline in carriage of PCV7 serotypes, overall

FIG. 85.16 Changes in invasive pneumococcal disease in US children <5 years by serotype groupings. PCV7 serotypes include 4, 6B, 9V, 14, 18C, 19F, and 23F. (From Pilishvili T, Lexau C, Farley MM, et al. Active Bacterial Core Surveillance/Emerging Infections Program. Sustained reductions in invasive pneumococcal disease in the era of conjugate vaccine. *J Infect Dis*. 2010;201:32–41.)

pneumococcal carriage did not change as a result of increases in carriage of nonvaccine serotypes, particularly serotypes 19A, 15A, 15B, 15C, 6C, 23A, 23B, and 35B. These changes in serotype distribution resulted in reduced transmission of PCV7 serotypes and a decline in IPD due to vaccine serotypes in all age groups, including infants less than 90 days of age and too young to be protected directly, as well as adults.⁴⁴⁴ In fact, Simonsen noted that 90% of the reduction in pneumococcal disease mortality occurred though herd immunity among adults 18 years and older (Table 85.10).⁵¹² Consistent with the observed differences in virulence between pneumococcal serotypes as discussed earlier, the current belief is that the lower capacity to produce disease following colonization with nonvaccine serotypes provides the explanation for the fall in invasive disease and pneumonia without a change in overall colonization. However, some of the non-PCV7 serotypes that emerged, specifically 19A and 7F, were associated with modest increases in invasive disease syndromes as well as pneumonia and otitis media both in children and adults. By 2007, the incidence of IPD due to serotype 19A had increased from 2.6 cases per 100,000 to 11.1 per 100,000 in children less than 5 years of age and represented nearly 40% of all IPD in this age group (Fig. 85.18).⁶¹²

FIG. 85.17 Percent of pneumococcal isolates within each sampling period by vaccine serotype grouping. PCV7 serotypes are 4, 6B, 9V, 14, 19C, 19F, and 23F. Additional 13 valent serotypes are 1, 3, 5, 6A, 7F, and 19A. Non-PCV13 serotypes are all other serotypes. (From Wroe PC, Lee GM, Finkelstein JA, et al. Pneumococcal carriage and antibiotic resistance in young children before 13-valent conjugate vaccine. *Pediatr Infect Dis J*. 2012;31:249–54.)

TABLE 85.10 Estimated PCV7 Reductions In Mortality During Hospitalizations for Invasive Pneumococcal Disease, Pneumococcal Pneumonia, and All-Cause Pneumonia: 1999–2000 Through 2004–05

Age Group	Estimated IPD Reduction		Estimated Pneumococcal Pneumonia (ICD9 481)		Estimated All-Cause Pneumonia Reduction

FIG. 85.18 Serotypes causing invasive pneumococcal disease in children <18 years in Massachusetts between October 31, 2009, and September 1, 2010. (From Yildirim I, Stevenson A, Hsu KK, et al. Evolving picture of invasive pneumococcal disease in Massachusetts children: a comparison of disease in 2007–2009 with earlier periods. *Pediatr Infect Dis J.* 2012;31:1016–21.)

Global experience with PCV7 demonstrated similar observations, with dramatic declines in IPD due to vaccine serotypes, initially in immunized children and subsequently in unimmunized adults, despite alternative vaccine schedules (to 3+1) being employed in many countries. The United Kingdom and parts of Canada introduced a schedule of 2 primary doses with a booster dose at 12 months of age (a 2+1 schedule), while Australia introduced a schedule of three primary doses without a booster (a 3+0 schedule).^{134,281,382} These schedules proved to be effective in both reducing IPD in children and creating indirect protection in unimmunized populations despite evidence that a two–primary dose series results in less serum antibody for serotypes 6B and 23F.^{295,350}

PCV13 was introduced in 2010 in the United States for healthy children through age 5 years, children with chronic illness through age 6 years, and children 6 through 18 years with sickle-cell disease, HIV, and other high-risk conditions. Proportionally, PCV13 serotypes comprised nearly 75% of all IPD in children less than 18 years of age, with 19A disease representing nearly 40% (see Fig. 85.18). Reports from multiple US surveillance programs^{290,389,610} demonstrate further declines in IPD in children under 5 years of age and a decline in disease due to serotype 19A.

Current surveillance data from the Centers for Disease Control and Prevention report that as of 2015, IPD in children less than 5 years of age had declined from 100 per 100,000 in 1998 to 9 per 100,000 in 2015 primarily due to a decline in vaccine serotypes, with little evidence of replacement (Fig. 85.19).⁹¹ The United Kingdom introduced PCV13 early in 2010 and has also reported a decline IPD due to PCV13 unique serotypes.³⁸¹ Similar declines in IPD in children have been reported from both high- and low-income countries following introduction of PCV13 or PCV10.^{142,249,563}

Although not licensed in the United States, PCV10 was also demonstrated to be efficacious against IPD using a population-based strategy, cluster randomized design in Finland. The reduction in vaccine-type IPD was 92% (95% CI, 86–95%) in children less than 2 years of age, with an overall reduction in IPD of 80%. A nonsignificant increase in nonvaccine type IPD was observed. The study demonstrated a substantial decrease in IPD rates among vaccine-eligible children and a smaller and temporally delayed reduction among older, unvaccinated children, confirming the presence of indirect protection.²⁸¹

Although invasive infections are the most dramatic part of the pneumococcal disease spectrum, respiratory infections such as otitis media are far more frequent.³⁴⁴ Efficacy studies have shown protection against AOM due to vaccine serotypes in children immunized with pneumococcal conjugate vaccines. In one study, PnCRM7 vaccine reduced the number of clinically diagnosed otitis media episodes by 7% (95%

CI, 4.1–7.9%).¹⁷¹ The effectiveness of the PnCRM7 vaccine against frequent otitis media was 9.3% (95% CI, 3.0–15.1%) when three episodes in 6 months or four in 12 months were counted, and 22.8% (95% CI, 6.7–36.2%) when a frequency of five episodes in 6 months or six in 12 months was considered. Children who received the vaccine were 20.1% (95% CI, 1.5–35.2%) less likely to require placement of a pressure-equalizing tube than controls. Otitis media was not a primary outcome measure in this study; the efficacy of the vaccine against otitis media caused by vaccine serotypes could therefore only be determined on children with spontaneously draining ears. A 66% calculated efficacy against disease caused by vaccine serotypes was found in this group.

A second study, conducted in Finland, looked at the efficacy of PnCRM7 vaccine against pneumococcal AOM caused by vaccine serotypes as well as overall episodes.¹⁵⁹ The children were monitored through 24 months of age. The efficacy of the vaccine in reducing AOM caused by vaccine serotypes was 57% (95% CI, 46–67%). The point estimate for efficacy of the vaccine in reducing all culture-confirmed pneumococcal AOM was 34%. The vaccine was not effective against nonvaccine pneumococcal serotypes, except against serotype 6A. The overall high protection provided against the serotypes included in the vaccine was offset partially by an increase in the number of episodes of otitis media caused by other serotypes of pneumococci and other pathogens. The overall reduction in the number of episodes of AOM of any cause in the pneumococcal vaccine group was 6%. Although this difference did not reach statistical significance, it was similar to the 7% reduction in AOM observed in the California study.⁵⁹ In addition, similar to the California study, by the time children reached the age of 4 to 5 years, tympanostomy tube placement was reduced 39% compared to controls.⁴²⁶

A third study was conducted by the same Finnish group in parallel with the study just described, with a different 7-valent vaccine (serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F conjugated to the meningococcal outer-membrane protein complex [OMPC]—PnOMPC7).³⁰¹ This vaccine was administered in 4 doses at 2, 4, 6, and 12 months of age. At 12 months of age, approximately 22% of the PnOMPC7 conjugate vaccine recipients received a nonconjugate 23-valent polysaccharide vaccine as a booster, while the others received a fourth dose of PnOMPC7. The efficacy of the vaccine in reducing the number of cases of otitis media caused by the serotypes included in the vaccine was 56%, with 25% for reduction of any pneumococcal AOM. However, there was no overall reduction in the number of episodes of otitis media, with nonvaccine serotype pneumococci and other pathogens producing replacement disease.

A fourth study, using an 11-valent PCV (the prototype for PCV10), conjugated to outer membrane protein D of nontypeable *H. influenzae*,

FIG. 85.19 Changes in the incidence of invasive pneumococcal disease (IPD) among children <5 years from 1998 through 2015 in the United States. Rates of IPD expressed as cases per 100,000 population are shown on the y-axis, and calendar year of surveillance on the x-axis. Blue bars represent overall IPD incidence, while the orange bars represent IPD incidence caused by serotypes included in the 13-valent pneumococcal conjugate vaccine (PCV13). PCV13 serotype: 1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F. (From Active Bacterial Core surveillance data. Available at <http://www.cdc.gov/pneumococcal/surveillance.html>.)

demonstrated a similar magnitude of protection against vaccine serotype AOM despite a markedly different study design.⁴⁵⁰ As the 11-valent PCV was conjugated to protein D from nontypeable *H. influenzae*, a 35% reduction in AOM episodes due to this pathogen was also reported, with an overall reduction in all episodes of AOM of approximately 33%. Further studies confirming the efficacy of PCV10, in which some serotypes are conjugated to protein D, are pending completion.

Since licensure and universal immunization of children younger than 2 years with PCV7, several studies have shown that the reduction in AOM exceeds that reported in clinical trials.^{216,443,582,621} Several hypotheses have been proposed to explain the observation. First, that with widespread immunization and dramatic reduction in nasopharyngeal carriage of vaccine serotypes, effectiveness against vaccine serotypes will increase to nearly 100%. Second, prevention of early episodes of pneumococcal AOM will change the natural history of AOM in children, reducing subsequent episodes.¹⁷⁴ Pneumococcal AOM is now primarily caused by nonvaccine serotypes.^{529,530}

Postmarketing studies from Israel demonstrated both direct protection following PCV13 against vaccine type pneumococcal otitis media and indirect protection reducing disease in children less than 4 months of age. In addition, Dagan and colleagues have proposed that prevention of early otitis media, and specifically early pneumococcal otitis media, had downstream benefits resulting in declines in the incidence of complex otitis media.^{51,124} Consistent with this hypothesis, tympanostomy tube insertion has declined following introduction of PCV13 in US children.¹²⁴

Reports of AOM and mastoiditis unresponsive to antimicrobial therapy requiring drainage and systemic antimicrobial therapy due to multidrug resistant serotype 19A increased prior to the introduction of PCV13.^{422,439} Antibiotic susceptibility and serotype distribution of pneumococcal isolates from children with AOM in France changed significantly after the introduction of the PCV-7 (2003) and PCV-13 (2010) vaccines.²⁹⁷ Resistance rates in 2001 and 2011 were 76.9% and 57.3% for penicillin, 43.0% and 29.8% for amoxicillin, and 28.6% and 13.0% for cefotaxime, respectively. After PCV-7 implementation, vaccine serotypes were markedly reduced, from 63.0% in 2001 to 13.2% in 2011, while the incidence of the additional six serotypes included in PCV-13, particularly serotype 19A, increased during this period.

Following introduction of PCV13, studies from Israel and Rochester, New York documented the decline in disease due to vaccine serotypes, specifically 19A.⁴³⁸

As most cases of pneumococcal pneumonia are nonbacteremic, the role of *S. pneumoniae* can best be demonstrated indirectly in vaccine probe studies by determining the proportion of disease reduction following vaccine implementation. In the northern California PnCRM7 vaccine study, 3711 clinically diagnosed episodes of pneumonia were identified by the age of 3.5 years.⁶⁰ The efficacy of the vaccine in reducing the incidence of clinical pneumonia was 6.0%. For children in whom a chest radiograph was obtained, an 8.9% reduction was observed; for those with a positive chest radiograph (defined as parenchymal infiltrates, consolidation, or effusion), a 22.7% (95% CI, 8.7–34.5%) decline in disease occurred. As the reduction in pneumonia was a secondary endpoint, the precision of the decline has some limitations. However, the findings suggest that more cases of clinically and radiologically proven pneumonia in children are caused by *S. pneumoniae* than previously suspected, with the reduction in disease extending beyond the “classic” lobar pneumonia pattern associated with *S. pneumoniae* to cases with non-lobar infiltrates. Comparable observations from South Africa documented a 22.1% reduction in children not infected with HIV immunized with PCV9.³¹³ Recent studies highlight the challenge of measuring the burden of pneumococcal pneumonia. Jain identified a pathogen in 1802 of the 2222 children (81%): one or more viruses in 1472 (66%), one or more bacteria in 175 (8%), and both bacterial and viral pathogens in 155 (7%). *S. pneumoniae* was identified in 4% of cases.²⁷³ Yet, in contrast, Griffin reported that annual pneumonia hospitalization rates declined in Tennessee children younger than 2 years old from 14.5 to 4.1 per 1,000 from pre-PCV years to PCV13 years (72%).²¹⁵ A 27% decline following introduction of PCV13 compared to the PCV7 era suggests that the role of the pneumococcus in hospitalized pediatric pneumonia is much larger than can be ascertained by traditional diagnostic approaches (Fig. 85.20).²⁷²

Additional supportive evidence that *S. pneumoniae* has an important role in a broader spectrum of respiratory infections can be derived from a study in southern Israel involving toddlers aged 12 to 35 months who attended daycare centers.¹²⁶ In this study, a 15% reduction in non-otitis media upper respiratory tract infection was reported. Episodes

FIG. 85.20 The paradox of pneumococcal pneumonia. (A) Pathogens detected in 980 cases of hospitalized pneumonia in children <2 years. AV, Adenovirus; COV, coronavirus; GAS, Group A *Streptococcus*; HMP, human metapneumovirus; HR, human rhinovirus; MP, mycoplasma pneumonia; PIV, parainfluenza virus 1-3; Inf A/B, influenza A or B; RSV, respiratory syncytial virus; SA, *Staphylococcus aureus*; SP, *Streptococcus pneumoniae*. (B) Monthly all-cause pneumonia hospitalizations in children <2 years. Pneumonia hospitalization rates decreased 27%, from 5.6 to 4.1 per 1000, after the switch from PCV7 to 13-valent pneumococcal conjugate vaccine in 2010. (A, Data from Jain S, Williams DJ, Arnold SR, et al. Community-acquired pneumonia requiring hospitalization among U.S. children. *N Engl J Med*. 2015;372(9):835-845. B, Modified from Griffin MR, Mitchel E, Moore MR, et al. Declines in pneumonia hospitalizations of children aged <2 years associated with the use of pneumococcal conjugate vaccines — Tennessee, 1998–2012. *MMWR Morb Mortal Wkly Rep*. 2014;63[44]:995-998.)

of lower respiratory tract disease—including bronchiolitis, cough, and pneumonia—were reduced. A reduction of 10% in the number of days that antibiotics were given for upper respiratory tract infections was achieved, as was a reduction of 47% for lower respiratory tract problems in the pneumococcal vaccine group.

Person-to-person spread is the major route of transmission for *S. pneumoniae*. The nonconjugate pneumococcal polysaccharide vaccines do not have a significant effect on carriage of *S. pneumoniae* in children and adults.^{121,356} In contrast, the conjugate vaccines have a significant effect on carriage that expands its public health value. Table 85.11 shows

selected studies conducted and published documenting the effect of pneumococcal vaccines on carriage of *S. pneumoniae*. Despite variations in the nature of the conjugate vaccines, populations, and the ages at which the vaccines were administered, a significant reduction in carriage of the serotypes included in the vaccine was observed in all studies. In most studies, serotype replacement was observed as the overall pneumococcal colonization remained relatively constant despite the decline in prevalence of vaccine serotypes.

Changes in nasopharyngeal colonization are important because they reduce exposure of unimmunized children and adults to these potential pathogens. This reduction has been demonstrated in studies of toddlers attending daycare centers who were vaccinated with a PnCRM9 vaccine or a control vaccine.¹¹⁶ In this study, the younger siblings of immunized and control children, who stayed home, were monitored. A marked reduction in the incidence of vaccine-type pneumococcal carriage was seen in the young siblings of those who were vaccinated with the PnCRM9 vaccine when compared with siblings of the controls. In a second study, Navajo and White Mountain Apache children younger than 2 years old were randomized according to their community of residence to receive either PnCRM7 or meningococcus C conjugate vaccine.³⁸⁰ A reduction in carriage of vaccine-associated serotypes was found both in infants who lived with a PnCRM7-vaccinated sibling and in those who did not have direct contact with a PnCRM7-vaccinated child but lived in a vaccine community, demonstrating the indirect protective effect of pneumococcal vaccination on those in the household. Because most antibiotic-resistant *S. pneumoniae* strains belong to a limited number of serotypes that are included in the conjugate pneumococcal vaccines or are related to these serotypes (see the section on [epidemiology and microbiology](#)), conjugate vaccines reduce disease, carriage, and spread of antibiotic-resistant *S. pneumoniae* and have an impact on the use of antibiotics. In all vaccine studies that evaluated the effect of conjugate vaccines on nasopharyngeal carriage of antibiotic-resistant *S. pneumoniae*, a reduction in carriage of such strains was observed^{116,121,123,127,370} (see [Table 85.11](#)). However, this reduction is both limited in time, as resistance had increased among the nonvaccine serotypes that replaced vaccine serotypes in carriage, and differs by geographic location depending on the serotypes most prevalent in a specific community.

Although invasive infections are the most dramatic part of the pneumococcal disease spectrum, respiratory infections such as otitis media and sinusitis occur far more frequently.³⁴⁴ In a study investigating current estimates of pneumococcal disease burden, clinical outcome, and vaccine efficacy, researchers estimated that for each annual US birth cohort, routine use of a 7-valent vaccine could prevent 12,000 cases of pneumococcal bacteremia and meningitis, 53,000 cases of pneumococcal pneumonia, and more than 1 million clinical cases of otitis media per year.³⁴⁴ Pneumonia has a greater impact globally than

does otitis media or even invasive infections because of its high mortality rate in children in the developing world.^{54,218,339} Thus, the protection conferred by the conjugate pneumococcal vaccines with regard to reduction in the number of episodes of otitis media, pneumonia, and other mucosal infections have an even greater public health impact on the burden of disease than on prevention of invasive infections.

Pneumococcal disease remains a burden on children throughout the globe. In young babies and children, the elderly, and those with serious comorbidities, the disease can be deadly. Progress in prevention, both in the development of effective vaccines and in implementation of vaccine delivery programs in developing countries, has exceeded expectations, resulting in decreased incidence of and mortality from invasive pneumococcal disease, including meningitis and both bacteremic and nonbacteremic pneumonia.³⁹⁵ The virtual elimination of nasopharyngeal colonization with vaccine serotypes enhances their public health value by reducing transmission of vaccine serotypes from children to adults, thereby reducing overall rates of pneumococcal disease. Vaccine failure is uncommon; Park et al. reported only 155 vaccine serotype infections identified by US surveillance systems with only 25 in fully vaccinated children, suggesting that the combination of direct and indirect effects protects infants as well as children with chronic illness from vaccine serotype disease.⁴²⁸ These findings demonstrate the major reduction in the burden of vaccine serotype pneumococcal disease in children associated with use of conjugate vaccines.

Nevertheless, potential challenges to the successful scenario observed to date are found in the distribution of disease due to nonvaccine serotypes. The US surveillance program reported a doubling of the proportion of children with comorbidities and IPD, which increased from 3% in 1998–1999 to 7% in 2007. In Massachusetts, a report noted that 16% of children with IPD have comorbidities that proportionately increased with age. Among the 155 cases of vaccine failure referred to earlier, a disproportionate proportion were reported to have comorbidities (37%).⁴²⁸ Ladhani also reported that comorbidities were present in 17.7% of UK children with IPD caused by PCV7 serotypes.³²⁵ Case-fatality rates also reflected great vulnerability of children with comorbidities, with mortality from pneumococcal disease (4.4% overall) higher for meningitis (11.0%) and for children with comorbidities (9.1%).

The most common comorbidities associated with pneumococcal disease reported include malignancies and immunocompromised conditions.²⁵⁵ Children with asthma, diabetes, and neurologic disorders such as seizures and muscular dystrophies have increased relative risk for IPD compared to age-matched healthy controls.⁵⁹³ Although the risk is modest with a single comorbidity, it escalates in children with two or more. Certainly, the high incidence of HIV and sickle-cell disease in developing countries in Africa are likely to result in these children being at high risk for nonvaccine serotype disease. Children with

malnutrition, tuberculosis, or exposed to secondhand smoke may also have higher risks for disease due to nonvaccine serotypes that erode vaccine success that requires ongoing surveillance and analysis.

CONCLUSIONS

Pneumococcal disease, most notably invasive disease and pneumonia, has decreased considerably, specifically in children in industrialized countries over the past decade, in association with the introduction of protein-conjugated polysaccharide vaccines as part of national childhood vaccination schedules. The decline in disease has been larger in unimmunized adults than in immunized children as a result of herd protection created by the reduction in carriage and transmission of vaccine serotypes. Decreases in antimicrobial-resistant vaccine serotypes also has resulted.

However, in developing countries, acute respiratory infections in general and pneumonia in particular remain the leading causes of morbidity and mortality.³⁷⁵ The mortality rate from respiratory infections in developing countries is estimated to be 10- to 30-fold higher than that in developed countries.^{397,398} Otitis media, although often not perceived as a severe problem in developing countries, may progress to chronic suppurative otitis media and acquired hearing loss in children.⁷ Global Alliance for Vaccines and Immunization programs have been critical in reducing the time line for introduction of pneumococcal conjugate vaccine into developing countries.

These advances have been limited by replacement of nasopharyngeal colonization by vaccine serotypes with nonvaccine and frequently antimicrobial-resistant serotypes, resulting in some erosion of vaccine effectiveness as a result of disease with nonvaccine serotypes in IPD and pneumonia as well as other respiratory pathogens in otitis media. These limitations, in turn, have been countered by the introduction of “second-generation” vaccines containing additional serotypes. These next-generation pneumococcal conjugate vaccines resulted in further declines in pneumococcal disease specifically due to the additional serotypes. However, as there are currently 94 recognized serotypes, replacement disease due to nonvaccine serotypes continues to be observed with variable incidence depending on the serotypes present. Evolution of additional serotypes in this genetically promiscuous organism is likely to continue. Development of alternative, broadly conserved vaccine targets that elicit protection against all pneumococcal strains would be very beneficial in the long term, yet currently identification of such potential vaccine antigens remains elusive.³⁸⁶

Miscellaneous Gram-Positive Cocci

86

Randall G. Fisher

The focus of this chapter is on relatively uncommon gram-positive cocci that are of importance because of their unusual antimicrobial sensitivities and increasing recognition as pathogens in hospitalized patients. The reader is referred to a review of these organisms for more details.²²

LEUCONOSTOC SPECIES

Bacteriology

Leuconostoc spp. are facultatively anaerobic, gram-positive cocci that usually appear in pairs or chains. They are catalase negative, Vogues-Proskauer positive, and leucine aminopeptidase positive. In addition, colonies often are α -hemolytic on blood agar and also may react with group D streptococcal antiserum. These properties are shared by viridans streptococci, with which *Leuconostoc* spp. often are confused.²⁴ They also may resemble enterococci, except that they are pyrrolidone carboxyl peptidase negative. Differences include the production of gas from glucose and high-level vancomycin resistance. *Leuconostoc* spp. have been divided into three subclusters²⁰; members of the first of these (the *L. mesenteroides* subcluster) are the only ones of human clinical importance. The most common pathogens are *L. mesenteroides*, *L. lactis*, *L. citreum*, *L. paramesenteroides*, and *L. pseudomesenteroides*.

Epidemiology

Leuconostoc spp. are found commonly on plants, especially sugar cane and leafy vegetables. They also are present in dairy products and wine.⁶⁷ They are used in the food industry as starter cultures in food production.^{42,81} Dextranucrase derived from *L. mesenteroides* is used to make gentio-oligosaccharides, which are prebiotics that have a lower degree of digestibility than inulin; these compounds are also toxic to human colon carcinoma cells in vitro.⁴⁷ Studies using culture methods have suggested that, although they occasionally are recovered from vaginal swabs in healthy individuals⁷¹ and from mucosal surfaces in some hospitalized individuals,³⁴ *Leuconostoc* spp. are not part of the normal human flora.⁴ Case reports of pediatric infection began to appear in the 1980s.^{15,35,65,88}

Pathophysiology

Leuconostoc spp. rarely are pathogenic. Underlying disease states or compromised immune system, gastrointestinal tract disease (especially short-gut syndrome), previous or current antibiotic therapy, venous or gastrointestinal tract access devices, recent invasive procedures, and

infancy are thought to be risk factors.^{19,21,34,67} In patients with short-gut syndrome, the presence of central venous catheters and disrupted bowel mucosa are likely the most important risks.²⁵ Frequently, the organisms are isolated as part of a polymicrobial infection after a patient has been treated with vancomycin.²² Of the first 21 cases reported in the English literature, 12 were in children, 10 of which occurred in patients younger than 1 year. Documented portals of entry include central lines,^{4,35} peritoneal dialysis and urinary catheters,⁹ and gastrostomy tubes.⁴⁰ A case of nosocomial meningitis apparently caused by frequent lumbar puncture after intracranial hemorrhage has been reported.³⁶ Contaminated enteral formula also has been implicated.^{10,40,62} One outbreak involving 42 patients in Spain was traced to contaminated total parenteral nutrition solution.⁵ Occasional sporadic cases without a known risk factor have been described, including one in a mildly premature baby who had not undergone instrumentation.^{15,34,56}

Clinical Manifestations

Bacteremia, heralded by fever and usually leukocytosis, is by far the most common clinical manifestation of *Leuconostoc* infection. Gastrointestinal disturbances, especially diarrhea, are common manifestations.⁴ Infants are prone to emesis. *Leuconostoc* bacteremia, in association with cough and chest radiographic findings consistent with pneumonia, was reported in a child with acquired immunodeficiency syndrome (AIDS).⁶⁷ *L. citreum* has been isolated from the lung tissue of a 33-year-old patient with AIDS who also had *Pneumocystis jiroveci* pneumonia.²⁸ Small necrotic cavities scattered through both lungs were associated with gram-positive cocci in tissue. Patients with associated dental infections,⁸⁸ peritonitis,²⁹ osteomyelitis,⁵⁸ and meningitis^{15,26} also have been described. Meningitis has been reported in an otherwise healthy 16-year-old patient and in a neonate with fatal infection despite high cerebrospinal fluid (CSF) bactericidal antibiotic titers.^{15,26} A nosocomial cluster of five cases of urinary tract infection caused by *L. pseudomesenteroides* (strictly a species of a new genus, *Weissella*)¹⁴ has been reported,⁹ as has a cluster of three cases of *Leuconostoc* septicemia in critically ill postsurgical patients.⁷⁴ In a series of 20 cases from Taiwan, 19 of the 20 had health care-associated bacteremia. Eleven of the 20 had an underlying malignancy, and the same number had been hospitalized for 30 days or more at the time the diagnosis was made.⁴⁹

Diagnosis

Cultures usually are positive within 24 to 48 hours. Identification of vancomycin-resistant *Streptococcus* should raise the suspicion of

Leuconostoc infection and prompt additional biochemical studies,⁶⁷ including gas production in MRS broth, failure to hydrolyze arginine, and delayed esculin hydrolysis. Accurate identification to the species level may require molecular techniques.¹⁷

Treatment

Treatment with relatively high doses of penicillin or ampicillin frequently is successful in eradicating infection. Many species produce biofilms⁵¹; when possible, access devices should be removed. *Leuconostocs* are most sensitive to the primitive β -lactam antibiotics, especially penicillin and ampicillin, although penicillin tolerance is a common finding.^{40,84} They also frequently are sensitive to erythromycin, cephalothin, and the aminoglycosides. *Leuconostocs* are variably resistant to clindamycin and trimethoprim-sulfamethoxazole. Resistance increases with later generations of cephalosporins.^{34,84} *Leuconostocs* are intrinsically vancomycin resistant because their pentapeptide cell wall precursors end in D-Ala-lactate rather than the usual D-Ala-alanine.³³ Vancomycin cannot bind the lactate. This mode of resistance is the same as that possessed by vancomycin-resistant enterococci. However, whereas resistance in enterococci is plasmid derived and transferable, in *Leuconostoc* spp. it is chromosomally mediated, constitutional, and not transferable.

PEDIOCOCCUS SPECIES

Bacteriology

Pediococci also are intrinsically vancomycin resistant, facultatively anaerobic gram-positive cocci. They appear most characteristically in tetrads on Gram staining, although they may appear in pairs or clusters.³¹ The genus name *Pediococcus* is derived from the Greek word *pedium*, which means "plane." This name, therefore, suggests that this is a genus of cocci that grow in a single plane. It is a misnomer, however, because pediococci are the only lactic acid bacteria that divide in two planes.²⁷ They are catalase and oxidase negative. They do not reduce nitrates, and no gas is produced in MRS broth.⁷⁹ They are pyrrolidone carboxylate peptidase negative.²² Most isolates react with Lancefield group D streptococcal antibodies.⁷⁹ They are leucine aminopeptidase positive, which distinguishes them from *Leuconostoc* spp.²³ They produce white, opaque, nonhemolytic colonies on sheep's blood agar. A new broth medium, a combination of 90% Iso-Sensitest broth and 10% MRS broth and called LAB susceptibility test medium, has been found to provide optimal support of growth and to yield the most accurate minimal inhibitory concentration values.⁴⁶

Pediococci produce powerful bacteriocins, which are substances that kill other bacteria. The bacteriocins of pediococci are active against other gram-positive organisms in particular¹³ but also are active against *Clostridium botulinum* spores,⁶³ some gram-negative organisms,⁸⁰ and *Listeria monocytogenes*. This has led to investigation of *P. pentosaceus* as a vaginal probiotic. Reports have suggested that some species of *Pediococcus* have antifungal activity⁵⁵; however, this activity in other studies has been found to be present only at low pH and has been attributed to acetic acid in the medium.⁸

Pediococcus acidilactici inhibits growth of *H. pylori* in vitro and provides benefit in a mouse model of *H. pylori* gastric ulcer disease.⁴³ Several species of *Pediococcus* have the characteristics of a good probiotic; they adhere to Caco-2 cells, possess desirable enzyme activities, and survive in feces for up to 2 weeks in human volunteers.^{2,50}

Epidemiology

Like leuconostocs and other lactic acid bacteria, pediococci are found on plants, in dairy products, and in alcohol-containing beverages, where certain species are associated with spoilage.⁸⁵ They also are used in the formation of silage⁴² and as starter cultures for some meat products. They are not thought to be part of the normal flora. They have been isolated from saliva and stool on rare occasion.⁷² Although formerly thought to be nonpathogenic, they now are considered rare opportunistic pathogens with minimal virulence.

Pathophysiology

Pediococci rarely are pathogenic. Many cases of blood isolates are found in patients without symptoms of infection or in polymicrobial cultures

in which the significance of the isolate could not be assessed adequately.⁵⁷ One patient with a clinical picture of septic shock in whom the only organism recovered was *P. pentosaceus* has been reported.¹⁶ Risk factors for bacteremia, with or without symptoms, appear to be the extremes of age, recent abdominal surgery or tube feeding, broad-spectrum antimicrobial therapy, and the presence of severe underlying disease states.⁵⁷ However, because the overall number of reported cases is small, the relative risks of these factors are uncertain.

Clinical Manifestations and Diagnosis

Most patients either are asymptomatic or have fever as the only symptom. Six of the first 12 reported cases of *Pediococcus* bacteremia had concomitant pneumonia. Fifty-six percent of adult patients either were receiving tube feeding or had undergone abdominal surgery within 30 days of isolation of the organism.⁵⁷ The three reported pediatric cases occurred in infants, and all had underlying gastrointestinal tract anomalies. A 16-day-old infant with congenital jejunoileal atresia had undergone surgical repair just 8 days before being evaluated.⁵⁷ Her acute illness was characterized by emesis and a 200-g weight loss. She was afebrile when initially examined. The second patient was a 64-day-old infant with gastroschisis who had undergone two abdominal surgical procedures.¹ His fever reached 38.6°C (101.5°F), and his peripheral white blood cell count was 38,000/mm³ with a significant left shift. The third patient was a 3-month-old female infant who had undergone surgical repair of gastroschisis on the first day of life.³ Lethargy, direct hyperbilirubinemia, and a CSF pleocytosis were noted. Blood cultures grew *Pediococcus* spp., and the CSF (obtained after initiation of antibiotics) was sterile. The patient responded to a 21-day course of ampicillin and gentamicin. An adult case of infective endocarditis in a man who had a history of bowel transplantation for short-gut syndrome⁴¹ and a case of persistent bacteremia in a patient with metastatic adenocarcinoma of the gallbladder have been reported⁸²; both responded rapidly to therapy with daptomycin.

Pediococci are isolated frequently in localized infections, especially from abdominal sites, but they are virtually always part of a polymicrobial process. The relative importance of pediococci in these sites is difficult to assess. A case of *Pediococcus* bacteremic pneumonia was reported in a previously healthy pregnant woman.⁷³ Among 31 cases of *Pediococcus* infection submitted to the U.S. Centers for Disease Control and Prevention laboratory, 17 were from blood culture isolates (including two reported cases of endocarditis) and four were associated with urinary tract infections. Other sources included catheter tips, wounds, peritoneal fluid, CSF, lung, and bone.²²

Diagnosis of infection with pediococci is established by identifying catalase-negative, vancomycin-resistant, gram-positive cocci in the characteristic tetrads. Many pediococci are misidentified initially as *Streptococcus equinus*, *S. constellatus*, or group D streptococcus, not *Enterococcus*. Reported cases of pediococcal infection may therefore represent only a fraction of the total number of infections.

Treatment

Pediococci generally are susceptible to penicillin, ampicillin, imipenem, clindamycin, and first- and second-generation cephalosporins. Although both imipenem and penicillin are highly active against pediococci, they do not appear to be bactericidal. Pediococci are moderately resistant to the quinolones, tetracycline,⁸⁵ and trimethoprim-sulfamethoxazole.⁷⁰ Pediococci, like leuconostocs, are intrinsically resistant to vancomycin. Resistance is not plasmid mediated, nor can it be transferred to other bacteria.⁸⁵ Sensitivity to ticarcillin and cefotaxime, when measured by agar dilution, is poor despite large zones of inhibition on disk susceptibility testing.⁸⁵ Occasionally inducible resistance to erythromycin is found, although most isolates remain sensitive. Aminoglycoside sensitivity is variable. Daptomycin appears to be active.

AEROCOCCUS SPECIES

Bacteriology

The genus *Aerococcus* contains at least five species, but only three, *A. viridans*, *A. sanguinicola*, and *A. urinae*, have known clinical significance. In earlier papers, *A. urinae* was referred to as *Aerococcus*-like organism.¹²

Aerococci are catalase-negative, nonmotile, gram-positive cocci that appear preferentially in tetrads but sometimes in pairs or clusters. These relatively slow-growing organisms produce small, well-delineated, translucent, α -hemolytic colonies on blood agar.¹¹ They also are weakly bile esculin positive and pyrrolidone carboxylate peptidase negative. They ferment mannose and mannitol.⁶⁸ Like enterococci, most aerococci will grow in 6.5% salt.⁴⁸

Epidemiology

Aerococci are distributed throughout the world and are contaminants of air and dust.³⁷ They also have been found on meat, on raw vegetables, and in small numbers on human skin.⁷ In hospitals, aerococci have been cultured from all areas, including operating suites and delivery rooms.⁴⁴ They also are found in saltwater, where they cause a fatal disease in lobsters.⁶⁴

Disease in humans is an uncommon event, and the organism usually is recovered from the bloodstream of patients with infective endocarditis. Most patients are elderly, but infection of infants and neonates also has been reported.^{61,64} A rapidly fatal bacteremia has been described in patients with profound neutropenia.⁴⁵ Aerococci are agents of urinary tract infection in elderly and institutionalized persons⁷⁸; these organisms can also cause pediatric urinary tract infections and even pyelonephritis, usually in the setting of obstructive uropathy.^{52,59}

Pathophysiology

In most circumstances, aerococci are saprophytic. The exact conditions that favor the development of infection have not been elucidated clearly. Some cases of *A. urinae* infection have occurred after genitourinary tract surgery. One case of septic arthritis developed after an elective abortion.⁸⁶ Septic arthritis of the hip developed in a paraplegic man; infection started in the urinary tract.³⁰ Immunocompromised patients are at higher risk, but infection in otherwise well persons has been described.⁶⁸ One report of meningitis in neonates found adherence of aerococci to inflammatory cells and suggested a role of as-yet-undefined adhesion factors.⁶¹ Work in laboratory animals also has shown that a protease isolated from *A. viridans* cleaves the hemagglutinin of influenza virus and potentiates both viral replication and disease in mice.⁷⁵ In vitro experiments show that the organism forms biofilms and causes platelet aggregation, features that explain why endocarditis is a common manifestation.⁷⁷

Clinical Manifestations

Most cases of *A. viridans* bacteremia have been found in association with signs and symptoms of subacute infective endocarditis. Severe disease requiring valve replacement surgery has been described, but not in pediatric patients.⁶ In one series of four cases of *A. viridans* infective endocarditis, two of the patients required surgical intervention.⁶⁹ *A. urinae* causes urinary tract infection with dysuria and frequency, usually in the absence of fever.¹¹ There have been several reports of foul-smelling urine in otherwise healthy children being caused by colonization of the urinary tract with *A. urinae*. Trimethylaminuria was suspected, but the odor went away with treatment.^{18,53} *Aerococcus* infection in childhood is an uncommon occurrence. One case of bacteremia in a 1-month-old infant has been reported.⁶⁴ The patient had a 2-day history of loose stools, irritability, and drowsiness and on physical examination was noted to have mottled skin, circumoral cyanosis, and agitation. CSF and urine studies were normal, but blood cultures exhibited pure growth of *A. viridans*. No predisposing factors were identified.

Nathavitharana and associates⁶¹ reported three cases of meningitis caused by *A. viridans*. They occurred in a 7-month-old female infant with jerking movements of the extremities, irritability, and a bulging fontanelle; a 5-month-old female infant with fever, decreased appetite, and generalized convulsions; and a 24-month-old girl whose illness was manifested as fever, vomiting, and the neurologic signs of truncal ataxia, flaccidity, and hypoactive deep tendon reflexes. All three patients had elevated CSF white blood cell counts with 55% to 93% segmented forms. Remarkably all these patients had a history of prolonged illness (1 week to 2 months) before being evaluated, in contrast to patients with other causes of bacterial meningitis. No risk factors for infection

were identified in any of these patients, who were thought to have normal immune function.

Swanson and colleagues⁸³ reported a case of penicillin-resistant *A. viridans* bacteremia in an 11-month-old girl receiving prophylactic penicillin for sickle-cell disease. The patient responded clinically to a 10-day course of therapy with cephalosporins.

Bone and joint infections and wound or other localized infections are exceedingly rare occurrences and not distinguishable from similar syndromes caused by more common organisms. However, there are a number of case reports of spondylodiscitis in patients with *A. urinae* bacteremia or infective endocarditis.^{60,87}

Diagnosis

Careful observation of both appearance on Gram stain and growth in culture is key to establishing the diagnosis of aerococcal infection. On Gram stain, aerococci resemble staphylococci. On blood agar, they resemble viridans group streptococci. One series revealed that 1% of 719 cultures called streptococci actually were aerococci⁶⁶; another study reclassified 3% of 168 cultures.⁷ In one study of 24 α -hemolytic, nonenterococcal bacterial isolates from urine, standard identification methods were compared with 16S rRNA sequencing and special biochemical profiling. Thirteen of the isolates were aerococci; all were identified correctly by sequencing, but typical procedures failed to differentiate them from nonaerococcal isolates. The ability to grow the organisms at 45°C improved the discrimination of standard testing.³² In their propensity toward tetrad formation, they mimic pediococci. However, all aerococci are vancomycin sensitive. In their bile esculin hydrolysis and growth in 6.5% salt, they resemble enterococci; unlike enterococci, however, aerococci are pyrrolidone carboxylate peptidase negative and do not form chains. Molecular modalities such as matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) are able to identify pediococci to the species level.⁷⁶

Treatment

Broth microdilution susceptibility testing of 128 isolates of *A. urinae* showed that they were all susceptible to penicillin, amoxicillin, cefotaxime, ceftriaxone, doxycycline, tetracycline, linezolid, meropenem, and vancomycin. A substantial portion had clindamycin and erythromycin minimum inhibitory concentrations (MICs) of greater than 0.25 µg/mL; 16% had levofloxacin MICs of greater than 2 µg/mL.³⁹ Reports of nonsusceptibility to penicillin or resistance to ceftriaxone have appeared but are the exception.⁵⁴ One report of an isolate resistant to vancomycin has been published.⁸⁹ They usually are intermediately susceptible or resistant to sulfonamides and aminoglycosides.^{7,37} Susceptibility testing for trimethoprim-sulfamethoxazole appears to be affected by the medium used in the testing.³⁸ One report suggests that *A. viridans* and *A. urinae* have distinct antibiograms⁴⁸; that is, *A. urinae* is more sensitive to penicillin and resistant to sulfonamides, whereas *A. viridans* is more resistant to penicillin and sensitive to the sulfonamides.⁷ Individual case reports do not confirm these in vitro observations, and no large clinical trials of antimicrobial susceptibility have been conducted.

Acknowledgments

I thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

SUBSECTION II Gram-Negative Cocci

87

Moraxella catarrhalis

Barbara W. Stechenberg

Once thought to be an unimportant commensal organism in the human respiratory tract, *Moraxella catarrhalis* now is recognized as an important pathogen in respiratory tract diseases, particularly otitis, sinusitis, and lower tract disease. The initial paper by Ghon and Pfeiffer²⁴ published in 1902 described gram-negative cocci in sputum referred to as *Micrococcus catarrhalis*. Since then, the organism has undergone several changes in nomenclature, first to *Neisseria catarrhalis* because of its resemblance to other *Neisseria* organisms. In 1970, in recognition of the contributions of Sarah Branham, the name was changed to *Branhamella catarrhalis*.¹¹ More recently, that this organism should be a member of the genus *Moraxella* has become clear; thus the name was changed to *M. catarrhalis*. With the transition in nomenclature, the past 2 decades have seen a parallel rebirth of this organism as a mucosal pathogen.

MICROBIOLOGY

M. catarrhalis is a gram-negative diplococcus that is morphologically indistinguishable from *Neisseria*. It has a tendency to resist decolorizing.¹ The organism is kidney shaped, with the flat sides abutting each other. The size varies, but it may be larger than meningococcus or gonococcus. However, the resemblance on sputum Gram stain or conjunctival smear to gonococcus can be striking and clinically confusing.

The organism grows well on blood or chocolate agar and forms small, opaque, grayish colonies that are circular and nonhemolytic. They have poor adhesion to the agar surface, on which they act like hockey pucks when pushed over the surface of the agar plate.¹⁷ The use of selective media such as modified Thayer-Martin or TV broth (Müller-Hinton broth supplemented with trimethoprim and vancomycin) increases the likelihood of recovering *M. catarrhalis* from the complex flora of the mucosal surfaces.

Isolates of *M. catarrhalis* cannot use maltose, glucose, lactose, or sucrose as carbohydrate sources. *M. catarrhalis* is oxidase-positive and produces deoxyribonuclease. Valuable differentiating tests are hydrolysis of DNA and tributyrin. Several rapid tests such as butyrate hydrolysis, Tween 80 hydrolysis, and selective DNase agar have been described.^{51,56} Fatty-acid analysis also has been used to identify atypical strains.

The surface of *M. catarrhalis* is composed of outer-membrane proteins, lipo-oligosaccharide, and pili. The organism does not appear to have a capsule, and the role of the pili is not defined well. By using a technique involving the collection of outer membrane vesicles, which are released into the culture medium, and then examining by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE), Bartos and Murphy⁶ identified eight proteins designated outer membrane proteins A through H. The outer membrane protein patterns of

strains from diverse geographic and clinical sources were strikingly homogeneous.

Preliminary studies of the lipo-oligosaccharide of *M. catarrhalis* show that it is more antigenically conserved than those of other gram-negative bacteria.⁴⁰ One study suggests that the lipo-oligosaccharide is not an adhesin, but its surface charge plays a critical role in the initial stage of attachment to human epithelial cells.² Several adhesins have been identified and may be potential candidates for a vaccine.⁴⁰

Restriction endonuclease analysis has been used as an epidemiologic tool to distinguish strains of *M. catarrhalis*. Patterson and associates⁴³ used the technique to evaluate a nosocomial outbreak and demonstrate the lack of association of other strains. Dickinson and coworkers¹⁶ used a similar technique to study isolates from children with otitis media.

PATHOGENESIS

The ability of *M. catarrhalis* to produce disease, particularly in sequestered areas such as the ear and lung, indicates that this organism possesses virulence mechanisms that allow it not only to grow in these anatomic sites but also to produce pathologic effects. However, a subset of strains of *M. catarrhalis* associated with selected virulence traits resulting in complement inactivation suggests that some strains are more virulent than others.^{9,55}

A body of literature concerning the immune response to *M. catarrhalis* and the antigenic composition of this organism has accumulated.^{12,13,35} Goldblatt and associates²⁵ demonstrated that children younger than 4 years possess immunoglobulin (Ig) G1 and IgG2 that recognize an 82-kDa outer membrane protein exclusively but that older children mount an IgG3 response to a broad range of outer membrane proteins. Faden and colleagues²² developed a technique to measure opsonic antibody with the use of outer membrane, antigen-coated beads. Convalescent sera opsonized homologous, antigen-coated beads significantly more often than did acute sera.

Unhanand and coworkers³³ used a murine model to study pulmonary clearance of *M. catarrhalis* from infected lungs. They investigated 10 strains and found marked variability in clearance rates and recruitment of phagocytic cells. With this model, Maciver and associates³⁷ actively immunized animals with the outer membrane vesicles of *M. catarrhalis* and passively immunized animals with rabbit antiserum raised against these vesicles. Both experiments resulted in enhanced pulmonary clearance of both homologous and heterologous strains. The same model has been used to evaluate the role of a large, antigenically conserved protein of *M. catarrhalis* in pulmonary clearance, as well as the role of outer membrane protein B in defense mechanisms of the lung.³¹ The

contribution of these proteins, as well as lipo-oligosaccharide, in host defense continues to unfold.

Initially thought to be an exclusively extracellular pathogen, *M. catarrhalis* invades multiple cell types. It is present intracellularly in human pharyngeal tissue, where it is a potential reservoir for persistent colonization.³⁰ The organism forms biofilms, which may contribute to its role in chronic otitis with effusion.^{28,29} Colonization of healthy children is characterized by genotypic heterogeneity, virulence gene diversity, and co-colonization with *Haemophilus influenzae*.⁵⁷

EPIDEMIOLOGY

M. catarrhalis is a normal inhabitant of the upper respiratory tract and is recovered exclusively from humans. The rate of colonization is highest in the early years and then declines steadily to less than 5% in adult life.⁵⁴ Prevalence studies report that as many as 50% of children are colonized with *M. catarrhalis*.^{33,38} Faden and associates²¹ monitored a large cohort of children from birth to 2 years of age. Sixty-six percent became colonized by the time they reached 1 year of age, and 77.5% did so by 2 years of age. The frequency of nasopharyngeal colonization was higher during visits for otitis media than during well-child visits. Otitis-prone children were colonized by 6 months of age. Restriction endonuclease analysis showed marked heterogeneity, with children acquiring and eliminating many different strains over time.^{21,43}

Numerous studies have documented the increased prevalence of *M. catarrhalis* as a pathogen in otitis media, either alone or as a copathogen.^{33,44} Shurin and colleagues⁴⁹ noted that isolation of *M. catarrhalis* from middle ear exudates increased from 6.4% between 1979 and 1980 to 26.5% between 1980 and 1982. A similar increase in *M. catarrhalis* as a pathogen in sinusitis has been reported.⁵⁸ In the pneumococcal conjugate vaccine (PCV7) era, a significantly higher proportion of PCV7-immunized children exhibit nasopharyngeal colonization with *M. catarrhalis*.⁴⁵

Once colonization of the oropharynx occurs, colonization of the tracheobronchial tree may follow, but usually only if other risk factors are operative. In adults, such risk factors include previous cardiorespiratory disease, smoking, use of corticosteroids, use of immunosuppressive agents, malignancy, and intercurrent viral illnesses.^{27,56} In children, many cases of pneumonia are associated with a preceding viral illness, prematurity, underlying lung disease, IgG deficiency, or other risk factors.

Nosocomial transmission has been well documented by DNA restriction endonuclease analysis.^{14,43} In pediatric intensive care units, endotracheal intubation and frequent suctioning have been identified as risk factors for the development of pneumonia and bacterial tracheitis.^{14,20}

Other interesting associations need to be investigated further. Seddon and associates⁴⁸ noted that colonization with *M. catarrhalis* occurred more commonly in asthmatic than in normal children. Whether the organism might be a trigger or pathogen in these children remains to be seen. Gottfarb and Brauner²⁶ found a high carriage rate of *M. catarrhalis* in children with severe persistent cough.

Infection with *M. catarrhalis* exhibits seasonality in both adults and children.^{27,49} Infection is much more likely to occur in the winter and spring months.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Otitis media caused by *M. catarrhalis* is indistinguishable clinically from otitis caused by other pathogens, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. *M. catarrhalis* may be isolated as a single agent or in combination with other organisms. There is some suggestion that otitis caused by this organism may be associated with less fever; a lower likelihood of a red, bulging membrane or perforation; and a lower C-reactive protein level.⁴⁰ Mastoiditis is not commonly seen with *M. catarrhalis*.

Because tympanocentesis usually is not performed in routine cases, the exact cause of an episode of acute otitis media generally is not known. One study found that *Moraxella* was an unusual organism as a single agent in children in whom acute otitis media had been treated

recently.²⁹ Nonetheless, in a study of persistent otitis, Pichichero and Pichichero⁴⁴ demonstrated *Moraxella* in 7% of specimens. The spontaneous resolution rate of *M. catarrhalis* may be high,⁴ and this fact should be considered when therapy is planned.

The clinical manifestations of acute sinusitis caused by *M. catarrhalis* are similar to those of other organisms; therefore selection of antibiotics should be made with consideration of this organism as a potential pathogen.

Lower respiratory tract disease caused by *M. catarrhalis* may have a broad clinical spectrum; however, because sputum samples often are not available in children, many cases documented in the literature have been severe. Berg and Bartley⁷ described five premature infants, all younger than 6 months of age, in whom precipitous clinical deterioration developed after 2 to 4 days of a prodrome consisting of cough, tachypnea, and intercostal retractions. They all required assisted ventilation, which is common in young infants with severe pneumonia.^{7,14,19} Some cases of *M. catarrhalis* pneumonia have been associated with bacteremia.

Underlying conditions such as leukemia, acquired immunodeficiency syndrome, and trauma have been reported to predispose a patient to the development of infection with *M. catarrhalis*.^{38,59} An association with Ig deficiency has been demonstrated in some patients with disease caused by this organism.¹² In adults, *M. catarrhalis* pneumonia occurs more commonly in patients with human immunodeficiency virus infection, malignancy, or chronic lung problems.^{25,56} The role of this organism in less severe manifestations probably is limited.³⁴

Bacterial tracheitis caused by *M. catarrhalis* has been reported in both immunocompromised hosts and those with normal immune systems.²⁰

M. catarrhalis also has been responsible for a wide variety of other infections. Urethritis caused by this organism can be mistaken for infection with *Neisseria gonorrhoeae*.⁵⁰ Several cases of conjunctivitis have been reported; when present in the newborn period, *M. catarrhalis* can mimic the ophthalmia neonatorum of *N. gonorrhoeae*.⁵² The relationship of neonatal infections to maternal vaginal carriage of *Moraxella* has not been established.⁴²

More severe infections with *M. catarrhalis* include meningitis and bacteremia, so this organism should be considered in appropriate circumstances, especially in immunocompromised children.

Children with *M. catarrhalis* bacteremia may have many different manifestations. Some patients have petechial or purpuric rashes, thus rendering the clinical picture indistinguishable from that of meningococemia. Others have been neutropenic and have required mechanical ventilation.⁸ Baron and Shapiro⁵ reported two cases of unsuspected bacteremia in children with nonspecific symptoms. Their manifestations were similar to those of children with occult pneumococcal bacteremia. An immunocompetent child with *M. catarrhalis* bacteremia and preseptal cellulitis has been reported.⁴⁷

Meningitis can occur from hematogenous spread of *M. catarrhalis* from the nasopharynx or as a consequence of ventriculoperitoneal shunt placement or surgery. Rarely suppurative arthritis has been seen in children and adults.^{32,39} Endocarditis is a rare occurrence, as is peritonitis.

TREATMENT

In the past, *M. catarrhalis* was susceptible to all β -lactam antibiotics. In the late 1970s, however, β -lactamase-producing strains of *M. catarrhalis* were isolated in Europe. In the United States, a parallel increase in the frequency of isolation of β -lactamase-producing *M. catarrhalis* has been noted, so it is not unusual for a laboratory to report that more than 90% of strains are β -lactamase producers.

The β -lactamases BRO-1, BRO-2, and BRO-3 are of chromosomal origin. BRO-1 is the most common β -lactamase in North American strains.¹⁵ Because of the high prevalence of β -lactamase-producing strains, many laboratories choose not to do any such testing. The β -lactamase inhibitors clavulanic acid, sulbactam, and tazobactam are active against the enzymes produced by *Moraxella*. Most β -lactamase-positive isolates will respond to achievable concentrations of β -lactam/ β -lactamase inhibitor antimicrobial combinations, cephalosporins, and cephamycins.^{18,23}

Among the oral cephalosporins active against β -lactamase-positive strains of *Moraxella*, the minimal inhibitory concentration increases two- to fourfold in the presence of the β -lactamase BRO-1 but not the β -lactamase BRO-2; cefixime is more active than are the older cephalosporins.⁴¹ Resistance to tetracycline (by the nontransferable tetB determinant) and erythromycin has been reported, but such resistance is a rare finding.^{10,46}

In vitro, *M. catarrhalis* usually is susceptible to ampicillin-sulbactam, amoxicillin-clavulanate, erythromycin, azithromycin, clarithromycin, trimethoprim-sulfamethoxazole, tetracyclines, chloramphenicol, fluoroquinolones (e.g., ciprofloxacin), aminoglycosides, and second- or third-generation cephalosporins, such as cefuroxime, cefprozil,

cefepodoxime, cefixime, cefdinir, and loracarbef.³⁶ Levofloxacin also exhibits good activity against *M. catarrhalis*.³ The *Moraxella* organism is resistant to clindamycin, vancomycin, and oxacillin.

PREVENTION

Prevention of nosocomial *M. catarrhalis* infection depends on sound practices of infection control, especially with regard to pulmonary toilet. Prevention of other infections with this organism has not been attempted. Development of a vaccine has been hampered by a lack of an animal model.

Meningococcal Disease

Lucila Marquez

Epidemic meningococcal meningitis was first described by Gaspard Vieusseux in Geneva in the spring of 1805. In a monograph entitled “The Disease Which Raged During the Spring of 1805,” he wrote:

*It commences suddenly with prostration of strength, often extreme: the face is distorted, the pulse feeble. There appears a violent pain in the head, especially over the forehead; then there comes pain of the heart or vomiting of greenish material, stiffness of the spine, and in infants, convulsions. In cases which were fatal, loss of consciousness occurred. The course of the disease is very rapid, termination by death or by cure. In most of the patients who died in 24 hours or a little after, the body is covered with purple spots at the moment of death or very little time afterward.*²³⁰

Today, *Neisseria meningitidis* continues to be a cause of endemic and epidemic disease. In the United States since 2012, approximately 550 cases of invasive meningococcal disease are reported each year, and 95% to 97% of these cases are sporadic.⁴⁶ Although cases in the United States are at a historic low, epidemics in developed and developing countries continue, and it is estimated that at least 1.2 million cases of invasive meningococcal disease occur annually, with an associated 135,000 deaths.¹¹⁸

The reader is referred to the excellent reviews of meningococcal disease that have been published recently.^{54,90,106}

MICROBIOLOGY

The *Neisseria* genus was named for Dr. Albert Neisser, who described the organism of gonorrhea in 1879. The genus *Neisseria* contains two species important in human disease, *N. gonorrhoeae* and *N. meningitidis*. In addition, several species are part of the normal flora of humans and animals. *N. sicca*, *N. lactamica*, *N. subflava*, *N. flavescens*, *N. mucosa*, *N. cinerea*, *N. polysaccharea*, and *N. elongata* are human commensals; they only occasionally cause human disease.¹⁴⁷

N. meningitidis is a gram-negative coccus, usually less than 1 μm in diameter. It classically occurs in pairs, with adjacent sides flattened, resembling kidney beans. Occasionally the organism divides in two planes at right angles to one another, which results in the formation of tetrads. The organisms are nonmotile, are aerobic (but facultatively anaerobic), produce catalase and oxidase, and may be encapsulated. *N. meningitidis* oxidizes glucose and maltose to acid. This distinguishes it from *N. gonorrhoeae*, which oxidizes only glucose. However, certain rare strains of *N. meningitidis* have been reported that fail to produce acid from either glucose or maltose. Fresh isolates have complex nutritional requirements, growing best on chocolate or blood agar.

Incubation in a humidified 10% carbon dioxide environment is not essential, but enhances growth. Morphologically the colonies are bluish-gray in appearance and will produce β -hemolysis after 48 to 72 hours of incubation on 5% horse blood agar.³²

N. meningitidis can be transformed by DNA originating in other *Neisseria* spp. Thus when a *Neisseria* spp. cohabiting the nasopharynx with *N. meningitidis* dies and releases its DNA, the coresident meningococcus can take up the DNA and incorporate it into its genome. Although this sequence of events is very rare, if the new DNA confers a selective advantage to the recipient meningococcus, the trait encoded by the incoming DNA may be retained in future progeny. This is the mechanism by which sulfonamide and penicillin G resistance have arisen in *N. meningitidis*.¹⁴⁷ Many commensal *Neisseria* spp., which inhabit the nasopharynx, are relatively resistant to penicillin G. DNA fragments from these commensal strains, encoding penicillin resistance, can be detected in penicillin-resistant *N. meningitidis*.²⁰¹ Transformation of new DNA into *N. meningitidis* also can introduce genes that modify the structure of the bacterium. Serotyping of groups A, B, and C meningococci has provided valuable macroepidemiologic information.⁸⁷ It is clear that as a population develops immunity to one capsular polysaccharide, the organism is capable of acquiring DNA encoding for an alternative capsule. Serogroup B to C and C to B switching has been reported.^{210,217,231} Additionally the serogroup W strain responsible for the Hajj pilgrim outbreak in 2000 was genetically associated with serogroup C strains.⁵⁴ In the United States, vaccination is not felt to be the driving force for capsular switching because serogroup B incidence declined even in the absence of vaccination against this serogroup, and more switching from serogroup B to C was observed in an epidemiologic study that compared pre- and postmeningococcal conjugate vaccine (MenACWY) periods.^{54,233} Horizontal gene transfer appears to occur from commensal *Neisseria* to *N. meningitidis*, offering products that aid the bacterium in surviving in the host or are involved in housekeeping functions.¹⁴³ This phenomenon is probably responsible for the occasional report of commensal *Neisseria* causing meningitis.¹⁴

In addition to the transformation route for varying the antigenic phenotype, meningococci also may exhibit phase variation, which allows for variance of the number of surface antigens. It has been estimated that there are at least 65 genes in *N. meningitidis* subject to phase variation including *porA*, which is an immunogenic outer membrane protein with more than 600 variants.^{80,224} Capsule synthesis may be switched on and off by this mechanism.

Like other gram-negative bacteria, the outer and inner cell membranes of *Neisseria* are phospholipid bilayers. These membranes sandwich a layer of peptidoglycan. Lipooligosaccharide, which is similar to the

lipopolysaccharide seen in gram-negative enteric bacteria, is associated with the outer leaflet of the outer cell membrane. Outer membrane proteins that function as porins are an integral part of the outer membrane. Some of these outer membrane proteins are opacity proteins and facilitate adherence and invasion.¹⁶² Beyond the outer membrane, meningococci possess a polysaccharide capsule that protects them from phagocytosis.

Meningococci also have pili, which seem to be important in some phases of adherence to host cells, colonization, and invasion. The genes that code for pili can be turned on and off, so that the organism at times may not express pili. A recent study reported that posttranslational modification of the type IV pili by phosphoglycerol altered the pili structure and destabilized the pili bundles, resulting in reduced bacterial aggregation on the mucosal surface, which allowed the organism to better cross epithelial monolayers to produce systemic invasion.⁴⁹ Antigenic variation of pili by a cassette mechanism allows the bacterium to escape the host's immune system.⁹⁹ In addition, both outer membrane proteins and lipooligosaccharide display antigenic variation by phase variation.

For epidemiologic purposes, meningococci are divided into serogroups, serotypes, and subtypes. Differences in capsular polysaccharides, outer membrane proteins, and lipooligosaccharides constitute the basis for these classifications. The capsular polysaccharides are antigenic and the basis for serogroup designation. Twelve serogroups currently are recognized: A, B, C, H, I, K, L, X, Y, Z, W-135, and 29E.²⁴⁰ Serogroup D has been reclassified as a serogroup C variant.⁹⁰ Serogroups A, B, C, W-135, X, and Y are the most common causes of invasive disease worldwide. Furthermore, more than 90% of meningococcal disease is caused by serogroups A, B, C, and Y.

Serotyping of organisms is based on antigenic differences in outer membrane proteins termed *porins*. Porins are protein channels in the outer membrane that permit nutrients and certain antibiotics to diffuse into the periplasmic space. A single locus encodes porin B, but two mutually exclusive alleles have antigenic differences. All meningococci have either antigenic class 2 or class 3 porin B. These differences permit serotyping. Subtypes are differentiated based on antigenic differences in porin A. This highly variable antigen is called a class 1 outer membrane protein. Multiple serotypes and subtypes have been identified. Antigenic specificity is achieved by the generation of monoclonal antibodies to the major protein (primarily class 2 or 3), lipooligosaccharide, and class 1 protein. The designation B:2a:P1.1:L3,7 indicates that the serogroup B strain is an "a" subtype of class 2 proteins, is a "1" of class 1 protein, and possesses two lipooligosaccharide antigens: 3 and 7.⁹³

Type 2 protein antigen is isolated from more than 50% of cases in the United States and Canada and is an antigenic determinant in serogroup B and C strains. These protein antigens not only are important as epidemiologic markers but also can induce protective bactericidal antibodies.⁸⁶

EPIDEMIOLOGY

Epidemiology in the United States

Invasive infections caused by *N. meningitidis* are reportable through the National Notifiable Surveillance System in the United States. The number of cases reported to the Centers for Disease Control and Prevention (CDC) between 2011 and 2014 were 845, 551, 556, and 564, for each year, respectively.^{43–46} The recent numbers reflect the lowest number of cases ever reported in the United States. In adolescents, the rate of meningococcal disease due to serogroups C, W, and Y dropped by 80% between 2004 and 2005 and 2012 and 2013 following introduction of quadrivalent meningococcal conjugate vaccine.⁵⁴

The Active Bacterial Core surveillance (ABCs) system in the United States tracks invasive disease caused by encapsulated organisms in selected counties of 10 states geographically dispersed throughout the country. This reporting system covers a population of 43 million people. In 2014, the overall incidence of invasive meningococcal disease for the United States was estimated to be 0.14 per 100,000 population.⁴⁶ Of cases reported through the ABCs system, 46% were meningitis, with a fatality rate of 6.9%; and 25% of cases were bacteremia, with a fatality rate of 20%. The case rate of invasive disease was similar between blacks

and whites, 0.16 per 100,000 population and 0.15 per 100,000, respectively. The serogroup distribution was 26% serogroup B, 36% serogroup C, 9% serogroup Y, and 28% other serogroups. These data exclude cases from Oregon due to hyperendemic rates in the state after a prolonged outbreak of serogroup B disease.⁴⁶

Certain serogroups are predominant causes of invasive disease depending on the age of the afflicted individuals. In the United States, serogroup B is responsible for 65% of infant disease. In contrast, disease in unvaccinated adolescents is principally due to serogroups C and Y, and disease in the elderly is due to serogroup Y.³⁴ Disease caused by serogroup W-135 is infrequent and, like disease in serogroup Y, has been associated with meningococcal pneumonia.^{199,234} The incidence of serogroup C and serogroup Y disease has increased in the United States over the past few years, associated with antigenic shifts involving outer membrane protein genes.¹⁰⁷ Outbreaks in the United States are typically due to serogroup C, although there have been a few notable outbreaks of serogroup B disease in recent years (see [Outbreaks](#) section).⁹⁰ Meningococcal disease in the United States peaks during the months of November through March.¹⁹⁹ The highest attack rate is seen in February, and the lowest attack rate occurs in September.

The risk for meningococcal disease is inversely related to age, with the highest rates of disease occurring in children younger than 1 year.⁴⁷ Between 2006 and 2012, the estimated annual incidence of meningococcal disease in infants was 3.30 cases per 100,000 infants.¹⁴⁵ However, in epidemics an age shift occurs, with older children, adolescents, and young adults more often affected.³⁹ A progressive increase in the development of protective antibodies against meningococci occurs between the ages of 2 and 12 years. In general, the development of bactericidal antibodies to meningococci increases in children at a rate of about 5% per year.⁹³ Neonates usually are protected if the mother has anti-meningococcal antibody by passive in utero immunoglobulin (Ig) G transfer.

International Epidemiology

Reduction in invasive serogroup C disease has been observed in several European countries, including the United Kingdom and Italy, after introduction of a conjugate serogroup C vaccine in the 1990s and 2000s.^{90,151,208} Overall in Europe, serogroup B is now responsible for the majority of cases of invasive disease, accounting for an estimated 60% to 72% of cases.⁹⁰ In the United Kingdom, it was estimated that serogroup B caused 85% of cases of meningococcal disease prior to the introduction of MenB vaccine.¹⁵¹ Other changes include an increase in disease due to serogroup Y observed in Northern European countries.⁹⁰

As was the case in Europe, Australia has also experienced a reduction in the number of cases due to serogroup C resulting from vaccination efforts.⁹⁰ Serogroup B now accounts for nearly three-quarters of invasive disease cases in the continent.¹⁷¹

In contrast, New Zealand has controlled an epidemic of serogroup B disease that began in 1996. At the peak of the epidemic in the early 2000s, the average incidence was 9.7 cases per 100,000 individuals. A tailor-made MenB vaccine that was introduced in 2004 subsequently controlled the epidemic. By 2013, the incidence of invasive disease due to serogroup B in New Zealand was down to 0.67 cases per 100,000 individuals.²⁰⁸

In developing countries, the incidence rate of invasive meningococcal disease is many times higher than in the United States (10 to 25 per 100,000 inhabitants per year).⁹⁷ Historically, the highest rate of meningococcal disease was found in a multicountry belt across sub-Saharan Africa, termed the *meningitis belt*, that had long been afflicted with endemic and epidemic serogroup A disease. Epidemics occurred in the meningitis belt each year, affecting thousands of individuals, typically during the dry season and decreasing once the rainy season started.^{177,184} Every 7 to 12 years, explosive outbreaks of disease occurred, causing extensive morbidity and mortality. The World Health Organization defines a meningococcal epidemic as more than 100 cases per 100,000 inhabitants per year, but in African epidemics the incidence could reach as high as 1000 per 100,000 inhabitants per year.¹¹⁸ Spread of clonal strains of serogroup A meningococcus may be a factor in Africa's unusually high rate of epidemic disease. Clonal strains can migrate transcontinentally and cause epidemics, such as the clonal serogroup A meningococcus,

electrophoretic type III-1 (ET III-1) that caused epidemics in China, Nepal, Saudi Arabia, Chad, and Kenya in the 1980s.^{156,158,177}

The epidemiology of meningococcal disease in Africa has been greatly impacted by the introduction of a conjugate meningococcal A vaccine (MenAfriVac) in 2010.⁹⁰ In 2009, the year prior to MenAfriVac introduction, 14 African countries implemented enhanced surveillance during the epidemic season and reported 88,199 suspected cases, including 5352 deaths, the largest number since a 1996 epidemic. However, the epidemiology has vastly changed since 2010. Mass vaccination campaigns have led to a dramatic drop in the incidence of meningococcal disease cases.¹⁷¹ Burkina Faso is one exemplary country where disease incidence fell by 99.8% after 94% vaccine coverage was achieved.⁵⁴ Similarly dramatic changes have occurred in Chad after mass vaccination.⁸⁸

Since the introduction of MenAfriVac, serogroup W has emerged as the predominant cause of meningococcal disease in the meningitis belt.¹⁷¹ Additionally in Africa the incidence of disease due to serogroup X has been increasing, even prior to the introduction of MenAfriVac.⁹⁰ MenX was responsible for more than half of the fatalities from meningococcal meningitis in Burkina Faso in 2010.^{185,243} As there is no licensed vaccine for serogroup X, this poses a real threat to disease control in this region of the world.

International outbreaks of *N. meningitidis* infections occurred in 1987 and 2000 and were associated with Muslims making the annual pilgrimage to Mecca. The disease spread to persons of all nationalities represented, some of whom returned home before becoming ill.^{158,181} In some cases, close contacts of travelers were infected. Several cases in US citizens were attributed to the outbreaks. The 1987 outbreak was linked to serogroup A, and the 2000 outbreak was due to serogroup W-135.^{8,158,181} Saudi Arabia now requires meningococcal vaccine for travelers entering the country to participate in the annual pilgrimage to Mecca.¹²⁹ Quadrivalent meningococcal vaccines should be used for travel to these areas given the need to protect against serogroups A and W.⁴

Serogroup W has emerged in other regions, including the southern cone of South America. In Argentina and Chile, serogroup W was responsible for 0% to 2% of cases of invasive disease in 2000, but by 2010 accounted for 50% to 55% of invasive cases.²⁰⁸ In Chile in 2012, serogroup W replaced serogroup B as the predominant cause of invasive meningococcal disease.¹³⁴ Similarly, England experienced the emergence of serogroup W, which led to incorporation of the quadrivalent conjugate vaccine for adolescents in the national program.¹³⁴

COLONIZATION AND CARRIAGE

The epidemiology of meningococcal disease was defined elegantly in a series of observations in New Jersey military recruits. An inverse correlation was noted between the age-related incidence of meningococcal disease in the United States and the prevalence of serum bactericidal activity against three pathogenic strains of *N. meningitidis*.^{93,94} Investigators prospectively studied all incoming recruits to Fort Dix and demonstrated that recruits who lacked bactericidal activity to case strains had a 38% attack rate if they were exposed and acquired a pathogenic meningococcus strain.⁹³ Usually nasopharyngeal carriage was an immunizing process. Carriage induced the formation of protective antibodies against homologous strains but also produced cross-reacting antibodies to heterologous strains of pathogenic meningococci. Antibody production typically was seen within 2 weeks of acquisition of carriage.^{93,94}

In addition to nasopharyngeal carriage, other processes may contribute to meningococcal antibody formation. Certain strains of cross-reacting bacteria, such as *Escherichia coli* and *Bacillus*, produce capsular polysaccharides that immunologically are identical to the capsules of meningococci serogroups A, B, and C. This is a potential immunizing source against invasive meningococcal disease in the general population.^{93,123,229}

Nasopharyngeal carriage of *N. meningitidis* is lowest in infants and children and highest in adolescents and young adults. Overall, 1 in 10 individuals in industrialized countries carry *N. meningitidis*, but the range varies from about 2% in young children to as high as 25% to 32% in adolescents and young adults.⁵⁴ One study determined that 2.4% of asymptomatic infants and children had a positive nasopharyngeal culture for *N. meningitidis* during a nonepidemic period.¹⁵⁰ A study of 1500 Norwegians found the carriage rate in persons 20 to 24 years of

age was 32.7% and in individuals beyond 25 years of age was 10%.³⁸ Other investigators have shown that approximately 20% of children harbor meningococcal species in their nasopharynx, but the majority of these isolates are atypical, nontypeable strains, which ferment lactose in addition to glucose and maltose.^{93,94}

Nasopharyngeal meningococcal carriage in household contacts of persons with documented meningococcal disease is about 10%.^{153,169,191} Several studies demonstrated that the carriage rate increases if infants or children are in the home.^{124,169} In one outbreak of serogroup C meningococcal disease, the carriage rates were 37.8% in households with a case in an infant, 17.5% in households with a case in a child, and 6.9% in households with disease in an adult.¹²³

Nasopharyngeal carriage is common after household contact with an index case, and colonization can persist for weeks to months. Without chemoprophylaxis, up to 35% of contacts become colonized by the eighth week. The median duration of carriage is 9 months.¹⁵⁰ However, in nearly 40% of individuals, it may exceed 16 months.⁹⁶ An association between smoking and increased rate of meningococcal carriage has been demonstrated.^{209,215}

RISK FACTORS FOR INVASIVE DISEASE

The factors responsible for converting nasopharyngeal colonization to invasive disease have not been firmly established. Many people who subsequently develop invasive disease are colonized shortly before the illness begins, usually within 2 weeks of colonization.³⁵ Likely these individuals lack bactericidal antibody and do not develop protective antibody after acquisition of the pathogenic strain. Some sequence types, such as ST-11, have the propensity to cause invasive disease, whereas others are more likely to be associated with asymptomatic carriage.^{35,90} Other risk factors associated with invasive disease include young age, crowding (e.g., military barracks and college dormitories),^{9,31,40} lower socioeconomic class,¹⁹⁸ concurrent upper respiratory tract infections,^{157,245} intimate kissing with multiple partners,²²¹ specific immune deficiencies (i.e., properdin or terminal complement),⁸¹ functional or anatomic asplenia,⁸⁵ and active or passive smoking, presumably due to its effects on mucosal immunity.^{83,90,209} Passive smoke has been implicated to increase the risk for meningococcal disease in children younger than 5 years by 7.5 times that of the general population.

Speculation as to the role of other upper respiratory tract pathogens in meningococcal disease prompted several observations. It was noted that the peak incidence of meningococcal infection mirrors the peaks of agents such as influenza and *Mycoplasma*. Several studies have shown an association between colonization or infection with respiratory tract viruses or *Mycoplasma* and the increased risk for development of meningococcal disease.^{36,113,157,204} Simultaneous outbreaks of meningococcal and influenza or echovirus infections have been documented.^{112,141,245} In addition, one study suggested that the incidence of meningococcal disease and the resultant morbidity and mortality increased in the 5 weeks after influenza-like syndromes.¹⁵⁷ It has been postulated that viral pathogens may temporarily affect the immune response and facilitate meningococcal disease. It is also possible that disruption of the normal respiratory epithelium occurs with viral infection, and this increases the likelihood that colonizing meningococci might become invasive.¹⁵⁷ Preceding viral respiratory tract disease is not a prerequisite for the establishment of meningococcal carriage or disease. However, its occurrence may increase the risk for invasive meningococcal disease.

A variety of host genetic factors also may influence susceptibility to invasive meningococcal disease, including deficiencies of components of the immune system (complement, properdin, and immunoglobulins) and single nucleotide polymorphisms (SNPs).⁹⁰ Individuals with complement component deficiencies (C3, properdin, Factor D, Factor H, or C5-C9) have up to a 10,000-fold increased risk for meningococcal disease.^{55,81} This usually is an inherited defect, and a history of other members of the family with meningococcal disease or repeated meningococcal infections may exist. Complement factor H is a complement-related protein, and certain polymorphisms in the complement factor H gene have been associated with an increased susceptibility to meningococcal disease.^{63,103} Acquired complement deficiencies associated with diseases such as systemic lupus erythematosus, nephrotic syndrome,

and chronic liver disease also are associated with increased risk for meningococcal disease.¹³⁷ A Russian study found the incidence of complement deficiency in first episodes of meningococcal disease to be about 1%.¹⁷⁹ In Italy, the prevalence of complement deficiency in patients with meningococcal meningitis was 17%.⁶¹ The decision of whom to screen for complement deficiency should be partly based on the prevalence of meningococcal disease in a given country. In countries where the incidence of meningococcal disease is high, complement deficiency is less likely to be found. In countries such as the United States, where the incidence is relatively low, complement screening should be considered because it has implications for family members who can be tested, immunized, and educated regarding their increased risk for meningococcal disease.

The chance of finding a complement or alternative pathway (properdin) deficiency substantially increases in patients with recurrent meningococcal disease or with uncommon serogroups. The prevalence of complement or properdin deficiency in a patient with infection by an unusual serogroup was found to range from 31% to 50%.^{82,165} Therefore screening all individuals with unusual serogroups is reasonable. CH₅₀ is a generally available test and will screen for combined activity of C1 to C9. If complement deficiency is found, the individual should receive meningococcal vaccines as recommended for high-risk individuals. In addition, family members should be screened for complement deficiency and should be educated about the disease.

Some investigators demonstrated that although persons with complement deficiency are more at risk for meningococcal disease, the disease they get often is mild. Meningococcal infection activates the complement system, and lipooligosaccharide present in the bacterium's outer membrane is probably responsible for the activation. In fatal cases, intense activation has continued until the time of death.²⁹ The case-fatality rate in complement-deficient individuals is about 3%.²⁰⁰ It is thought that complement-deficient individuals are unable to maintain the high-level complement pathway activation and therefore have less severe disease.

Properdin deficiency, which impairs activation of the alternative complement pathway, is X-linked and has been associated with fulminant meningococcal disease.^{67,82} The case-fatality rate in one kindred was 75%.²² Screening of individuals with exceptionally fulminant disease or individuals who have a family history of meningococcal infections should be considered. AP₅₀ will screen for properdin deficiency in the alternative complement pathway.

SNPs can influence progression to or protection from meningococcal disease. Variants in mannose-binding lectin (MBL), Toll-like receptors (TLR) 2 and 4, and nucleotide oligomerization domain (NOD) 2 have all been associated with progression to meningococcal disease.⁹⁰ MBL is a pattern recognition receptor and a component of the innate immune system. Patients with meningococcal disease during childhood have a significantly increased incidence of structural mutations in the genes coding for MBL, leading to deficient MBL function in contrast to that in healthy age-matched controls.⁷⁸ Similarly human TLR4 mutations are associated with susceptibility to invasive meningococcal disease in infancy.⁷⁷ In one study, a TLR4 SNP was associated with mortality, skin grafting, and limb loss.⁹⁰ In contrast, SNPs of TLR9 have been shown to be protective of invasive meningococcal infections.⁹⁰

PATHOLOGY AND PATHOGENESIS

The mechanisms by which meningococci invade humans are only partially understood. We do know that encapsulated, typeable meningococci are virulent, whereas nonencapsulated strains are relatively nonpathogenic. The presence of a polysaccharide capsule enhances invasiveness by resisting opsonization and subsequent phagocytosis. Even among encapsulated strains, differences in virulence between case and carrier strains of *N. meningitidis* have been demonstrated in an animal model.¹¹¹

The human nasopharynx is the only natural reservoir of *N. meningitidis*.²¹² Once pathogenic meningococci have colonized the respiratory tract of susceptible persons, either the organisms become invasive or the individual develops antibody to the organism, conferring immunity. Meningococci adhere to nonciliated, columnar epithelial cells in the

nasopharynx via pili. Binding induces endocytosis of the organism into the epithelial cell, and the bacteria may penetrate the epithelial barrier via phagocytotic vacuoles.²¹¹ If antibody is insufficient and invasion occurs, the individual may become bacteremic. Occasionally unsuspected meningococcal bacteremia has been detected on blood culture and spontaneously cleared on a follow-up culture without antibiotics.²¹⁵ However, in most cases, this does not occur and the individual becomes progressively sicker. Bacteria in the blood may seed the meninges and cause meningitis.

Meningococci are gram-negative organisms, and lipooligosaccharide is a major component of the bacterial cell membrane. Meningococci release blebs from their surfaces that contain an outer membrane laden with lipooligosaccharide. Lipooligosaccharide is a potent endotoxin and concentrations of it correlate with severity of disease.^{27–29} Lipooligosaccharide induces release of a host of inflammatory and antiinflammatory mediators whose concentrations are also correlated with severity of disease: tumor necrosis factor- α (TNF- α), γ -interferon, interleukin-1 (IL-1), IL-6, IL-8, IL-10, and IL-1 receptor antagonist.^{91,138,225,226,236} TNF- α downregulates thrombomodulin expression on endothelial cells, leading to decreased activity of proteins S and C.^{56,163} Like TNF- α , many of the mediators directly or indirectly contribute to the formation of a pro-coagulant state, which results in the formation of microthrombi that are characteristically found in the skin, digits, extremities, and organs. The disseminated intravascular coagulation commonly seen in meningococcemia is believed to be a consequence of activation of the coagulation system by endotoxin.¹⁹⁵ Experimental animal work suggests a synergistic effect of meningococcal endotoxin and materials egested from leukocytes containing meningococci in the initiation of disseminated intravascular coagulation.⁶⁹

Cytokines play an important role in the development of shock frequently seen in meningococcemia. Cytokine release causes neutrophil activation and upregulation of adhesion molecules that may promote endothelial damage and capillary leak.⁷⁵ Vasodilation also may occur secondary to increased production of nitric oxide by endothelial cells.¹⁵⁵ Compensatory vasoconstriction of splanchnic, skin, and renal vessels may subsequently not suffice to maintain adequate blood pressure. Endotoxin-related or cytokine-mediated cardiac dysfunction also may contribute to development of heart failure and hypotension.¹⁷² Profound capillary leak in the pulmonary bed may lead to the development of acute respiratory distress syndrome (ARDS). The pathologic purpuric lesions seen in fulminant meningococcal disease are similar to those that the generalized Shwartzman reaction induces in rabbits by endotoxin. Pathologically these lesions show evidence of microthrombi in the small dermal vessels, endothelial damage, and hemorrhage. Inflammatory vasculitis is mediated by upregulation of endothelial adhesion molecules, neutrophil activation, and effects of cytokines and bacterial endotoxin.^{11,60,110} Circulating concentrations of endotoxin in patients with meningococcemia may be 50 to 100 times that of other gram-negative infections.¹⁸⁰ In addition, meningococcal endotoxin is more potent than endotoxin from enteric bacilli.⁶⁴

A pathologic study of 200 fatal meningococcal infections illustrates the ability of the meningococcus to affect virtually any organ, either directly or indirectly.¹⁰⁵ Approximately 40% of patients in this study had both meningococcemia and meningitis. Except for adults with meningitis, the average survival time for all cases was 72 hours or less. The major organ systems involved at autopsy in these 200 cases were heart, central nervous system (CNS), skin, mucous and serous membranes, and adrenals. Myocarditis occurred in 78% of cases. Cutaneous hemorrhages occurred in 69% of the fatal infections and ranged from isolated petechiae to diffuse purpura. Acute meningitis was noted at autopsy in 68%, with brain abscesses noted in two patients. In almost half of the cases with acute meningococcemia, *N. meningitidis* was isolated from otherwise normal cerebrospinal fluid (CSF). Adrenal hemorrhage and necrosis were found in 48% of autopsy cases. Diffuse adrenal hemorrhage occurred in approximately 50% of adult cases and in more than 80% of pediatric cases. Focal areas of inflammation and petechial hemorrhage were seen in many other tissues, including the synovium, skeletal muscle, and the tracheobronchial tree. An association was seen between the pathologic findings and the infecting serogroup of *N. meningitidis*. Serogroup A infections most frequently were associated

with encephalitis; serogroups B and C infections were associated with necrotizing myocarditis.

CLINICAL MANIFESTATIONS AND DIFFERENTIAL DIAGNOSIS

The spectrum of disease caused by *N. meningitidis* ranges from asymptomatic transient bacteremia, which clears spontaneously, to fulminant sepsis resulting in death only a few hours from symptom onset.²¹⁵ In 2006, Kaplan and colleagues (the US Multicenter Meningococcal Surveillance Study Group)¹²² reviewed 159 episodes of invasive meningococcal disease seen at 10 children's hospitals in the United States between January 2001 and March 2005. Meningitis was the most common manifestation of disease seen in 70% of cases. In this study, 27% of children had bacteremia alone and 4.4% had fulminant disease. Hypotension was present in 10% and thrombocytopenia in 6% on admission. The overall mortality rate was 8% and was significantly greater in children older than 10 years compared to those younger than 11 years ($P < .01$).

Meningococemia and Meningitis

Serious or invasive disease usually presents in one of two ways: meningococemia or meningitis (either with or without meningococemia). It is important to consider other etiologies in the differential diagnosis of meningococemia (Box 88.1).

The signs and symptoms of meningococemia are variable. Early on, evidence of an upper respiratory tract infection may be seen, including coryza, pharyngitis, tonsillitis, and laryngitis. Patients generally are febrile, with complaints of headache, lethargy, and vomiting. Severe myalgias with muscle tenderness and joint pain also may be the presenting symptom.¹¹⁴ The typical patient with meningococemia has a short history of upper respiratory tract symptoms, fever, and a hemorrhagic rash. The patient often develops signs of severe circulatory collapse. It is not unusual for purpura and shock to develop within hours of the first onset of symptoms.

The skin manifestations of meningococemia range from diffuse mottling to extensive purpuric lesions (Figs. 88.1 and 88.2). Unfortunately some variation exists in the type of rash seen. Petechiae or purpura are present in 50% to 60% of patients.^{124,242} In a multicenter study of invasive

disease in children, 55% of patients had petechiae and 38% had purpura.¹²² Maculopapular rash alone is reported in 10% to 13% of patients.^{152,242} This makes differentiation from a viral exanthem particularly difficult. A pink macular rash resembling early varicella is another variant sometimes seen in children with meningococemia; these lesions often are tender. They may occur in crops, as do the petechiae, and are seen most frequently on the trunk and extremities.^{71,109} Furthermore 20% to 30% of children may have no rash at presentation.²⁴²

The finding of petechiae or purpura in a febrile child should increase the index of suspicion for meningococemia or other serious disease (e.g., infectious, neoplastic, immunologic). Acral distribution of a rash is particularly worrisome for meningococemia or another infectious vasculitic process. In two studies involving more than 200 patients with fever and petechiae (not purpura), 8.0% to 20.2% had invasive bacterial disease.^{228,242} Seven to 10% of the total group had infections

FIG. 88.1 Purpuric lesions are seen on the trunk and extremities of a young child with meningococemia.

BOX 88.1 Differential Diagnosis Meningococemia

Infectious

Rocky Mountain spotted fever
Ehrlichiosis
Streptococcal *pneumoniae* sepsis
Haemophilus influenzae type b sepsis
Group A streptococcus sepsis
Staphylococcus aureus sepsis
Other bacterial sepsis with disseminated intravascular coagulation (i.e., enteric gram-negative organisms)
Infective endocarditis
Gonococemia
Rat bite fever
Typhus
Secondary syphilis

Noninfectious

Henoch-Schönlein purpura
Acute hemorrhagic edema of infancy
Idiopathic thrombocytopenic purpura
Collagen vascular disease
Neoplastic processes

FIG. 88.2 Close-up of leg lesions in the child shown in Fig. 88.1.

caused by *N. meningitidis*. Therefore it seems reasonable to obtain blood cultures on most febrile patients with petechiae. Lumbar puncture should be performed if clinically indicated or if the blood culture ultimately is positive. Antibiotic therapy should include coverage for meningococcus.

Wong and colleagues²⁴² reviewed 100 cases of meningococcal infections in children seen at their institution between 1985 and 1988. Fifty-five percent of patients had meningitis. Leukopenia (white blood cell count $<5000/\text{mm}^3$) was present in 21%, and thrombocytopenia was noted in 14%. Eleven percent of those with culture-positive meningitis had no CSF abnormalities on chemistries or examination. Other laboratory abnormalities seen in patients with sepsis or shock include abnormal coagulation panels (disseminated intravascular coagulation), acidosis, and abnormal liver function studies.

Purpura is noted in 16% to 24% of patients.^{182,242} When purpura is extensive and accompanied by shock, it is referred to as *purpura fulminans*. Acquired protein S and C deficiencies have been described in some patients with purpura fulminans.^{182,183} One study showed a mortality rate of 50% in patients who developed purpura. Progressive purpura was accompanied by declining protein C levels, and the level of protein C was related inversely to the clinical severity of disease.¹⁸²

Patients with meningitis often are febrile, with headache, vomiting, irritability, stiff neck, and sometimes seizures. A history of lethargy may be present, or the patient may be obtunded. In neonates, physical findings of meningismus, such as Kernig and Brudzinski signs, often are absent. The anterior fontanelle, if open, may be full and tense.

Hyponatremia is seen in some patients with meningitis. Inappropriate secretion of antidiuretic hormone is the mechanism. In a study of 43 children with meningococcal meningitis, 7% developed syndrome of inappropriate secretion of antidiuretic hormone.⁷⁶

The most common neurologic complications of meningitis are cerebral edema, cranial nerve palsies (especially hearing loss), subdural effusions or empyemas, cortical vein thrombosis, cerebral infarctions, and hydrocephalus (see section on **Prognosis, Morbidity, and Mortality**).

Cerebral edema and cranial nerve palsies may be seen at presentation or develop shortly thereafter. Sixth- or third-nerve palsies are suggestive of increased intracranial pressure and impending herniation, respectively. The development of either of these signs indicates an urgent intracranial process. Auditory testing should be performed on all patients with meningitis after recovery.

Subdural effusions or empyemas should be considered in patients with fever persisting after 8 days of therapy, vomiting, or development of signs of increased intracranial pressure after the initial few days of treatment. Drainage is recommended only if the effusions are infected (empyemas) or are large enough to produce either focal neurologic signs or increased intracranial pressure.¹⁷⁰

Vascular thrombosis and cerebral infarction can be due to arterial or venous thrombosis. Venous thrombosis is more common and generally is not seen before the second week. Hemorrhagic infarction of the brain may occur then. Cerebral infarction also may be seen in patients without arterial or venous thrombosis who are in shock with prolonged hypotension and cerebral ischemia. Cerebral infarction in these individuals is an early event.

Hydrocephalus occurs most frequently in young children and those with delayed diagnosis or severe disease. It tends to present 3 to 4 weeks after the onset of illness. Inflammation, with collagen deposition and proliferation of fibroblasts in the meninges, produces an obstruction to the flow of CSF. Progressive increase in head circumference should alert the clinicians to the possibility of hydrocephalus.¹⁷⁰ Imaging (i.e., computed tomography or magnetic resonance imaging) studies are diagnostic.

Neonatal meningococcemia and meningitis are uncommon but have been reported. In one report, a 2-week-old infant died after a brief febrile illness with both CSF and blood cultures positive for meningococcus. Maternal endocervical colonization was documented. In addition, the mother's pharyngeal culture grew *N. meningitidis*.¹²⁰ If endocervical colonization by *N. meningitidis* is found prenatally, treatment with antibiotics should be considered in an attempt to eradicate colonization before delivery or intrapartum antibiotics should be given. Ceftriaxone

would seem to be a reasonable choice. Rifampin and ciprofloxacin are not advocated for use during pregnancy.

Chronic Meningococcemia

Chronic meningococcemia, first described in 1902, is defined as meningococcal septicemia without meningeal symptoms in which fever has persisted for at least a week before any antibiotic therapy.^{73,168} Benoit¹⁷ reviewed 148 cases of chronic meningococcemia in the United States in 1963 in patients ranging in age from 3 months to 62 years. The major symptoms included fever and chills (present in 100% of patients), skin rash (93.2%), arthralgias (70.3%), and headache (61.5%). The patients generally were not in a toxic state and were in good health before becoming infected. The mean duration of illness before diagnosis was 6 to 8 weeks (range, 1 to 40 weeks). Symptoms tended to be intermittent; the rash often appeared in association with fever and then disappeared over the next several days. Bacteremia also was intermittent in some patients. In the Benoit study, on average, five blood cultures were obtained before meningococci were isolated. However, after a blood culture yielded the organism, most subsequent cultures were positive. In children, some investigators report that it is common to isolate the organism in the first blood culture.¹³⁹ Arthralgias also tended to be intermittent in nature.

In Benoit's series,¹⁷ almost 40% of the patients with chronic meningococcemia developed localizing complications. The meninges were the most common site of localization; meningitis developed in 15.5% of patients. Other localized infections included carditis, nephritis, epididymitis, conjunctivitis, iritis, and retinitis. In only one instance was an organism recovered from a joint. The average duration of meningococcemia in those patients with complications was 10.2 weeks, in contrast to 4 to 8 weeks in patients without any localization.

The diagnosis is established by identifying the organism in blood cultures. Antibiotic therapy results in prompt defervescence and dramatic recovery.

The pathophysiologic mechanisms permitting chronic meningococcemia remain unclear. No evidence suggests that the organisms are less virulent than other meningococci; thus, a defect in host immunity has been suggested. A hypersensitivity basis for this disease has been postulated, and it is theorized that the skin changes and arthritis may be secondary to antigen-antibody complexes.¹⁶⁹ In contrast to acute meningococcemia, bacteria are almost never found by biopsy or culture of skin lesions. The histologic findings of the skin lesions are distinct from those seen in skin lesions of patients with acute meningococcemia.^{17,105,169}

Meningococcal Pneumonia

Meningococcal pneumonia occurs in conjunction with meningococcemia or meningitis in 8% to 15% of cases.¹²⁸ However, meningococcus also can play a role as a primary respiratory pathogen.

Primary meningococcal pneumonia, once considered a rare disease, now is recognized as the most common form of meningococcal disease in certain military recruit populations and has been reported to cause 4.5% of all bacterial pneumonias in a general hospital population.^{128,142}

Patients with preceding viral pneumonias are at risk for meningococcal pneumonia; more than 100 cases of meningococcal pneumonia occurred during the influenza pandemic of 1918 and 1919. In addition to disease among military recruits, nosocomial acquisition of meningococcal pneumonia in hospitalized patients has been reported.⁵³

The diagnosis of meningococcal pneumonia is difficult because isolation of the organism from the sputum does not distinguish a meningococcal carrier from an individual with meningococcal pneumonia. In addition, routine sputum cultures do not include media selective for meningococcus. Blood cultures are positive in only 15% of individuals.¹²⁸

Koppes and associates¹²⁸ reported on 68 cases of meningococcal pneumonia; diagnostic criteria included a compatible clinical syndrome and isolation of *N. meningitidis* from pleural fluid or blood.¹²⁸ All 68 meningococcal pneumonia cases were serogroup Y; during the same period, 10 cases of meningococcemia and 6 cases of meningitis were caused by serogroup Y. The high ratio of pneumonia to meningitis in

this study suggests that serogroup Y organisms may be more likely to cause pneumonia than other serogroups, which has been substantiated by other investigators.^{186,198} Pneumonia caused by serogroup B or C meningococci has been reported, usually in association with meningococcemia or meningitis.²⁴¹

Primary meningococcal pneumonia usually is associated with a gradual onset of symptoms. Rales and fever are found in most patients, and 80% have pharyngitis. The radiograph often shows involvement of lower lobes with patchy alveolar infiltrates. More than one lobe is involved in 40% of cases. Twenty-five percent have pleural effusions. Petechiae, purpura, or shock were not present in any of the patients with pneumonia reported by Koppes and colleagues.¹²⁸

The pathogenesis of this disease is thought to be pulmonary infection via droplet inhalation. The epidemiologic importance of meningococcal pneumonia was emphasized in a report from the CDC discussing nosocomial transmission of serogroup Y *N. meningitidis* in oncology patients.⁵³ The index case had meningococcal pneumonia. One other patient in an adjacent room developed meningococcal bacteremia; in three additional patients, serogroup Y *N. meningitidis* was isolated from nasopharyngeal cultures. Airborne dissemination seemed to be the mode of transmission. Respiratory isolation for a patient with suspected meningococcal pneumonia is indicated.

Penicillin therapy of penicillin-sensitive meningococcal pneumonia results in a prompt clinical response. Of the patients reported by Koppes and colleagues,¹²⁸ 93% were afebrile after 3 days of therapy. Third-generation cephalosporins, such as ceftriaxone, may be the current drugs of choice pending definitive identification.

Other Meningococcal Syndromes

Conjunctivitis

Primary meningococcal conjunctivitis is indistinguishable clinically from acute bacterial conjunctivitis caused by other organisms. Usually it presents in children as the acute onset of unilateral purulent conjunctivitis.¹⁵ It has been reported in individuals from 2 days of age to adulthood.⁸ Gram stain of the purulent material typically shows gram-negative diplococci that may sometimes be confused with gonococcal organisms. Barquet and colleagues¹⁶ showed that 44% of the isolates were serogroup B meningococci.

The complications of primary meningococcal conjunctivitis reported by Barquet and colleagues¹⁶ included sepsis or meningitis in approximately 18% of patients. The symptoms of systemic meningococcal disease occurred 3 to 96 hours after the onset of the conjunctivitis (mean, 41 hours). Patients treated only with topical therapy at the time of conjunctivitis were 19 times more likely to develop systemic disease than were patients treated with systemic therapy ($P = .001$). Ocular complications occurred in 15.5% of patients and included corneal ulcers (10.7%), keratitis, hemorrhage, and iritis.

Pharyngitis

The diagnosis of meningococcal pharyngitis is difficult because, like group A β -hemolytic streptococci, the isolation of meningococcus from the pharynx does not establish that this organism is the etiologic agent. In fact, most individuals who harbor meningococci in their nasopharynxes are asymptomatic carriers. However, Banks¹³ noted overt nasopharyngitis in one third of patients with meningococcal sepsis or meningitis. Pizzi,¹⁷⁸ describing a severe epidemic of meningococcal meningitis, noted that individuals with sore throats often had a pure culture of meningococci.¹⁸⁰ Olcen and associates¹⁶⁹ cultured family members of 21 consecutive cases of meningococcal disease and found that 61% of family members with sore throat or other upper respiratory tract symptoms were meningococcal carriers, in contrast to 14% of asymptomatic family members.¹⁶⁹

On occasion, culture samples are obtained in individuals in the community with symptomatic pharyngitis, and the laboratory reports growth of *N. meningitidis*. If the patient is febrile but otherwise appears well, we recommend a blood culture and intramuscular or intravenous ceftriaxone. If the blood culture result is negative, the patient should be treated with an antibiotic. If the patient is afebrile and asymptomatic at the time the culture results are obtained, we recommend eradication

of the organism using one of the antibiotics recommended for chemoprophylaxis (see discussion of chemoprophylaxis).

Arthritis

Meningococcal arthritis occurs primarily in adults. The overall incidence, as a complication of bacteremia, is approximately 2% to 14%.^{98,242} Meningococcal arthritis has two forms. The first is seen within the first few days of treatment and is characterized by severe arthralgias and few objective signs of joint inflammation. It is suggested that the pathogenesis of this arthritis is an inflammatory response to viable organisms that have seeded the synovium during the initial bacteremia. The second, more common form appears to be an immune complex phenomenon. It usually is noted 3 to 7 days after the recognition of meningococcemia, often at a time when the patient appears to be improving from the meningitis or sepsis. The knee, wrist, elbow, and ankle joints are involved most commonly.⁹⁸

In both forms, the arthritis usually is monoarticular or oligoarticular with an effusion, with minimal pain, erythema, and limitation of motion. It is very unusual to culture organisms from the effusion; joint fluid culture yields meningococci in fewer than 10% of cases. The exception to this is a child with suppurative arthritis on initial presentation. In one study, 8% of patients with meningococcal infections had arthritis; 75% had positive culture results when cultures were obtained before receiving antibiotics.^{241,242}

Synovial fluid leukocyte counts vary widely, but counts greater than 100,000/mm³ have been reported.¹⁷⁶ The appearance of arthritis often is accompanied by a rise in temperature; in 7 of 47 patients with arthritis, a characteristic skin lesion appeared at the same time.⁹⁹ These lesions began as skin hyperpigmentation but progressed to vesiculation and ulceration; biopsies showed vasculitis. Additional evidence of concurrent vasculitis is suggested by reports of patients developing episcleritis and mild proteinuria simultaneously with arthritis.⁹⁹

On histologic examination, the synovium is infiltrated with mononuclear cells that contain IgM, C3, and meningococcal antigen.⁹⁷ This strongly suggests an immune complex-mediated disease. No specific therapy is indicated, and the arthritis resolves spontaneously. Controversy exists regarding the role of intermittent closed drainage of the joint space.²³ Permanent joint deformity is uncommon in this disease, occurring in approximately 10% of cases.²⁰³ Edwards and Baker⁷⁴ reported immune-mediated complications of meningococcal disease in 10% of the 86 children followed prospectively. More than 83% were serogroup B, although late-onset arthritis and vasculitis also have been reported with disease due to serogroups A and C.

Permanent joint damage is unusual, occurring in about 1.5% of patients with arthritis. Potential sequelae include ankylosis, decreased range of motion, and bone necrosis.¹³⁷

Pericarditis and Myocarditis

Pericarditis as a complication of meningococcal disease occurs in 3% to 5% of cases, although one series reported a 19% incidence in 32 patients with meningococcal meningitis.^{72,159} It generally occurs in patients with meningococcemia but has been reported as an isolated event without septicemia or meningitis.¹⁰⁸

Pericarditis is presumed to be a late complication of meningococcal disease because clinical symptoms such as fever, dyspnea, or substernal chest pain (or even cardiac tamponade) usually do not appear until the fourth to the seventh day of illness. However, several investigators have noted early evidence of pericarditis based on electrocardiographic or radiographic data of patients examined at the time of hospital admission.

Because most symptomatic pericardial effusions develop late in the course of the illness, are serous, and are sterile, the pathophysiologic mechanism is presumed to be an immune complex reaction. Uncontrolled studies report the successful use of steroids in the treatment of this complication. However, one report documents pericarditis and the development of tamponade in a patient receiving steroids.¹⁷³ Although an immune complex phenomenon is the most likely scenario, *N. meningitidis* may cause as many as 20% of cases of purulent pericarditis.³⁵

The clinical course of meningococcal pericarditis usually is benign, but pericardial compression requiring pericardiocentesis occurs.¹⁷⁵ Early

relapses also have been reported, but these were self-limited. The development of constrictive pericarditis requiring pericardectomy has been reported.^{173,205,235}

Myocarditis was noted at autopsy in 78% of patients with fatal meningococcal disease.¹⁰⁵ Myocarditis was noted most often in adults but was more severe when it occurred in children. Rosenblatt and colleagues¹⁹⁶ noted myocarditis at autopsy in 10 of 12 children with fatal meningococcal infection. On pathologic examination, these cases showed collections of inflammatory cells in the myocardial interstitium and focal extravasation of erythrocytes with acute vasculitis. Abscesses and endocarditis were not seen. Inflammation occasionally may involve the atrioventricular node and has been reported as a cause of sudden death in a patient recovering from meningococcal meningitis.¹⁹³

Miscellaneous Meningococcal Infections

Several unusual syndromes have been reported, including primary meningococcal pericarditis,²²⁸ mesenteric adenitis,¹³³ peritonitis,¹³³ and genitourinary infections.⁷⁹

PROGNOSIS, MORBIDITY, AND MORTALITY

Various scoring systems have been devised in an attempt to predict prognosis in patients with meningococcal disease. Most prognostic scoring systems and clinical reviews agree that purpura fulminans and shock uniformly are poor prognostic signs. These scoring systems were reviewed in an article by Kirsch and colleagues.¹²⁷

The Glasgow Meningococcal Septicaemia Prognostic Score (GMSPS) is a validated scoring system developed to clinically assess patients and facilitate admission of the most severely ill children to intensive care units.^{206,218} This scoring system, which evaluates seven key items (hypotension, difference in skin-core temperature, coma, acute deterioration, absence of meningismus, progressive purpura, and base deficit) has been used by many to define entry criteria into clinical trials.

In a review of 100 cases of meningococcal disease at the Los Angeles Children's Hospital, five features were identified that correlated with poor prognosis: shock or seizures on presentation, hypothermia, total white blood cell count less than 5000/mm³,¹¹⁸ platelet count less than 100,000/mm³, and development of purpura fulminans. The overall mortality in this series was 10%.²⁴²

Long-term complications can occur in 20% to nearly 60% of patients.¹⁵¹ Survivors of meningitis can be left with neurologic and hearing impairment. In an Australian study, any neurologic impairment occurred in 8.5% of cases with CNS infection.¹⁵¹ Neurologic sequelae are much more common in patients with meningitis, but complications such as cerebral infarction also can be seen in children with meningococemia and shock.¹⁶⁹ In studies of adults with meningococcal meningitis, cognitive impairment was identified in 28% of patients, hearing impairment in 8% of patients, and cranial nerve palsies in 3% of patients.³⁵ In a United States multicenter study conducted from 2001 to 2005, hearing loss occurred in 12.5% of children with meningitis.¹²²

Sequelae of meningococemia are disfiguring and debilitating. In one study, skin necrosis occurred in 9.4% of children, and 2.4% required skin grafts.¹²² In this study, 1% of children underwent amputations; one child lost all four limbs. However, limb amputation has been reported in as many as 20% of survivors, although incidence is likely influenced by geography.⁹⁰ Other consequences include renal failure.⁵⁰

The overall mortality of invasive meningococcal disease in the United States is 7% to 19%.^{122,166,197,213} Individuals with only meningitis have a lower case-fatality rate than those with bacteremia or an isolate from another source (2% vs. 12%).¹⁹⁷ Presumably this is a function of the virulence of the organism, ability of the immune system to contain the infection, or both. Case-fatality rates also differ by serogroup and are higher in W-135 disease (21%) than in serogroup C (14%), Y (9%), or B (6%).¹⁹⁷

Evidence suggests a genetic component exists in host cytokine production that may be associated with severity of disease. Westendorp and associates²³⁷ reported that families with low TNF production or high IL-10 production are at increased risk for fatal outcomes with meningococcal disease. Variants of proinflammatory host genes (TNF- α ,

IL-1) might be linked to severity of disease. Read and colleagues found that homozygosity of certain alleles at the IL-1 locus increased risk for death in individuals with meningococcal disease and suggested that IL-1 genotype may be associated with fatal outcomes.¹⁹⁰

DIAGNOSIS

The gold standard for diagnosis is based on recovering the organism from blood, CSF, or skin lesions. Blood culture alone is positive in about 50% of patients who have not received antibiotics.²⁴² Rapid diagnosis can be made by Gram stain of CSF in patients with meningitis, which reveals characteristic gram-negative diplococci in approximately 90% of samples obtained before starting antibiotics.³⁵ However, caution should be exercised in relying solely on the Gram stain to determine the initial antibiotic regimen. Overdecolorized gram-positive cocci of *Streptococcus pneumoniae* on occasion have been confused with meningococci on Gram stain. Thus broad-spectrum antibiotic therapy should be initiated pending identification of the organism by culture.

In patients who have skin lesions, a rapid presumptive diagnosis of meningococemia often can be made by needle aspiration and Gram stain of a skin lesion, which reveals gram-negative diplococci in 50% to 80% of patients with acute meningococcal infections.^{35,227} Culturing the obtained aspirate increases the yield further. Skin lesion gram stain and culture may be useful in individuals pretreated with antibiotics as they have been shown to be positive up to 45 hours and 13 hours, respectively, after administration of antibiotics.³⁵ Correlation of the Gram stain with the clinical presentation is important because disseminated gonococcal infections also may present with skin lesions that yield gram-negative diplococci on Gram stain.

Latex agglutination has been used to detect circulating antigen in serum, CSF, and urine of patients with meningococcal disease.²³⁸ Latex agglutinin tests using serum and urine are not recommended. Cross-reactions with certain *E. coli* K1 (cause of neonatal meningitis) or *Bacillus* strains may occur.

Polymerase chain reaction (PCR) may be very helpful in the diagnosis of patients who have partially treated meningococemia or meningitis. Confirmation of the diagnosis impacts patient management, follow-up, and prompt institution of chemoprophylaxis to contacts. Once antibiotics have been given, the chances that a blood culture will be positive decreases to less than 5%.³⁷ CSF culture can be negative as early as 15 minutes after antibiotics and is expected to be negative when obtained 2 or more hours afterwards.³⁵ One study showed the sensitivity and specificity of PCR for *N. meningitidis* to be 91% in cerebrospinal fluid specimens. Treatment with antibiotics before the test did not decrease the test's sensitivity or specificity.¹⁶⁴ One report from the United Kingdom describes use of a multiplex PCR assay for the simultaneous detection of *N. meningitidis*, *H. influenzae*, and *S. pneumoniae* from clinical samples of CSF and whole blood. Corless and colleagues⁵⁸ found that the sensitivities for detection of the three organisms ranged from 88.4% to 91.8%, with 100% specificity. A 2012 article from China and Australia reported development of a multiplex PCR assay for detection of 12 meningococcal serogroups.²⁴⁶ Commercially available assays such as this would greatly facilitate etiologic diagnosis in children with sepsis or meningitis. Currently meningococcal PCR is in use in the United Kingdom but is not routinely available in the United States. Investigators in the United Kingdom have utilized quantitative PCR of CSF in patients with culture-proved meningococcal disease. In their experience, the sensitivity of CSF PCR was 89% for detection of *N. meningitidis*. In addition, they noted that patients with serogroup B infection had extremely high quantities of bacteria within the CSF regardless of the peripheral blood bacterial quantitation.⁶²

TREATMENT

The first antibiotics used for meningococcal infections were the sulfonamides, and their use lowered the death rate to 5% to 10%.¹⁰⁰ With the emergence of sulfa-resistant strains, penicillin was added to the regimen and is still recommended for susceptible meningococcal infections. In the late 1980s, reports began to appear of meningococci relatively resistant to penicillin. The mechanism of resistance is reduced binding

affinity of penicillin-binding proteins, though resistance is not entirely explained by mutations in PBP2.¹⁰⁴ Relatively resistant strains have been reported in the United States, Canada, Europe, South Africa, Romania, and Croatia.^{25,116,174,216,245}

In a United States multicenter descriptive study of invasive disease in children conducted between 2001 and 2005, only one penicillin-intermediate isolate was identified, and no penicillin-resistant isolates were found.¹²² Later, in a United States study by Harcourt and colleagues, susceptibility testing was performed on isolates collected through the ABCs system and found that, overall, 10.3% of isolates in 2004, 2008, 2010, and 2011 were penicillin-intermediate.¹⁰⁴ The overall trend in the United States is concerning given that only 3% of isolates in 1997 were penicillin-intermediate compared to 16.7% in 2010.¹⁰⁴ Yet the clinical significance of intermediate resistance to penicillin is unknown, and the proportion of penicillin-intermediate isolates in fatal cases in the United States was low.^{54,104}

In the study that tested ABC system isolates, 3 of 466 isolates tested between 2004 and 2010 were penicillin-resistant.¹⁰⁴ There were no resistant isolates in 2011. The three penicillin-resistant isolates were serogroup Y, which was also the serogroup most likely to have intermediate resistance to penicillin. Isolates that are absolutely resistant to penicillin (minimum inhibitory concentration >1.0 µg/mL) have also been documented from Spain and the United Kingdom.^{174,216} These European strains had acquired a gonococcal plasmid encoding for the production of a β-lactamase.²¹⁶ Ceftriaxone-nonsusceptible strains have been reported from India.¹⁴⁹

In 2009, ciprofloxacin-resistant isolates were identified from four unrelated patients with invasive meningococcal disease in three U.S. states. Three of the cases were infected with serogroup B meningococcus and one with serogroup Y meningococcus. Genetic studies suggested that the Y strain acquired resistance by a point mutation. However, the B strains may have acquired resistance through horizontal gene transfer from *N. lactamica*, a commensal organism carried in the nasopharynx.²⁴⁴ Resistance to rifampin has also been reported but is sporadic.¹⁰⁴

Prompt institution of antibiotic therapy in suspected meningococcal infections may be life saving. Children who present with fever and purpura should be considered to have meningococcemia until proved otherwise while recognizing that other pathogens or disease processes may present with fever and purpura. A purpura fulminans-like presentation also has rarely been described in infections due to *Staphylococcus aureus*,¹³¹ group A streptococcus,⁷⁰ group B streptococcus, and overt sepsis with other organisms causing disseminated intravascular coagulation. Antibiotics should be administered as soon as possible. A systematic review of the effectiveness of antibiotics given before admission concluded that “the data are consistent with benefit when a substantial proportion of cases are treated.”¹⁰¹ If possible, blood cultures should be drawn before antibiotic administration, but specimen collection should not delay administration of antibiotics. A lumbar puncture can be performed in stable patients, but the procedure should not delay antibiotic administration. CSF obtained after antibiotic therapy may be sterile, but pleocytosis should be apparent and other diagnostic modalities such as PCR can be considered. Patients who are unstable or have significant coagulopathy should have the lumbar puncture deferred. Shortly after administration of bactericidal antibiotics, some patients have marked clinical deterioration, including hypotension and sometimes death. Rapid liberation of endotoxin (and resultant stimulation of cytokine release)¹⁵³ from lysing organisms may be the cause of this phenomenon.

The clinical presentation of *N. meningitidis* meningitis may be similar to that of meningitis caused by *S. pneumoniae* or *H. influenzae*. Empirical antibiotic therapy should therefore take into consideration the most likely pathogens. In children older than 1 month of age with meningitis, vancomycin and ceftriaxone is an appropriate regimen until a definitive diagnosis is made. Similarly, empirical therapy for children younger than 1 month of age includes ampicillin, with consideration given to the addition of vancomycin.¹⁹⁹

The 2015 American Academy of Pediatrics Red Book states that, for cases in the United States, treatment can be narrowed to penicillin once *Neisseria meningitidis* is identified. However, continuation of ceftriaxone

is recommended for travelers from areas where penicillin resistance has been reported, including Spain, Italy, and parts of Africa.⁶ Some experts recommend susceptibility testing before narrowing to penicillin, and the previously described study that documented penicillin resistance in the United States supports the need to ascertain penicillin susceptibility prior to narrowing from empirical therapy. In the United States, large microbiology laboratories should be able to perform susceptibility testing. Susceptibility testing should especially be considered in circumstances in which resistance is clinically or epidemiologically suspected.

For penicillin-susceptible meningococcemia or meningitis, intravenous penicillin G 300,000 U/kg per day (maximum 12 million U/day) given in divided doses every 4 to 6 hours for 7 days, is effective. Third-generation cephalosporins, such as ceftriaxone 100 mg/kg per day intravenously in two divided doses, also are effective. The recommended treatment for patients with anaphylactic reactions to penicillin is chloramphenicol. Meropenem is a treatment option for those with severe allergies, although there is a small proportion of penicillin-allergic patients who may cross-react with the carbapenems.⁵

In confirmed cases of meningococcal disease, comparisons of penicillin G with ceftriaxone have shown ceftriaxone to be as efficacious. Necrotic skin lesions were seen more commonly in the penicillin group, but otherwise complication and mortality rates were equivalent.²²² Meningococcal disease has been treated successfully with ceftriaxone intravenously in both the 80 to 100 mg/kg per day in one daily dose and 100 mg/kg per day in two divided doses regimens.²²²

With all cases of meningococcal disease, eradicating colonization of the index case is important (see discussion of chemoprophylaxis). One dose of ceftriaxone effectively eradicates nasal carriage.

Steroid administration in patients with septic shock and meningococcemia is controversial, but several studies have reported adrenal insufficiency (or partial adrenal insufficiency) in 10.3% to 16.9% of severely ill children with meningococcemia.^{246,566,192} For patients with Waterhouse-Friderichsen syndrome, treatment with steroids is indicated. However, treatment of meningococcal meningitis with steroids has been debated in the literature for years. Steroid proponents point to the *Haemophilus influenzae* type b meningitis and *Streptococcus pneumoniae* studies, in which treatment with steroids decreases hearing loss and may reduce neurologic sequelae. They postulate that steroids, through antiinflammatory effects, may decrease polymorphonuclear neutrophils, macrophages, and cytokines in the CNS and thus decrease CNS immune-mediated damage and hearing loss. Steroid opponents say that no conclusive studies show steroids to be of benefit in meningococcal meningitis and that risks include gastrointestinal ulceration, decreased penetration of antibiotics into the CNS (because of decreased meningeal inflammation), and steroid psychosis. If steroids are used, it seems prudent to use them early (preferably close to the time the first dose of antibiotic is administered). However, antibiotics should never be withheld waiting for steroids to be given.

Experimental and Adjunctive Therapies

Many adjunctive and experimental therapies have been tried, including antiendotoxin therapies and protein C concentrate infusions. Two antiendotoxin therapies have been evaluated in clinical trials: HA-1A and recombinant bactericidal/permeability increasing protein (rBPI). HA-1A, a human monoclonal antibody to endotoxin, was evaluated in a randomized, double-blind, placebo-controlled trial in 269 children with severe meningococcemia that was published in 1999. Although the 28-day mortality rate in the treatment group was 18% in contrast to 28% in the placebo group, this was not statistically significant ($P = .11$).⁶⁸ BPI is a naturally occurring protein in neutrophil azurophilic granules that binds to and neutralizes the effects of endotoxin. A randomized, double-blind, placebo-controlled trial that was published in 2000 studied rBPI in 393 children with presumed meningococcal disease. There was no difference in mortality rates (7.4% rBPI vs. 9.9% placebo). There was a trend in reduction of amputations in the treatment group that approached statistical significance ($P = .067$).¹⁴⁰

The efficacy of recombinant human activated protein C in sepsis has been studied extensively. In a large randomized, placebo-controlled

trial of 1690 adult patients with severe sepsis, known as the PROWESS study, a reduction in mortality was demonstrated, but the treatment group had an increased risk for bleeding.^{18,21} A large study, published in 2007, compared activated protein C to placebo in children with severe sepsis.¹⁶¹ The study was terminated by the Data and Safety Monitoring Board because of a low likelihood of improved outcome in the treatment group. Subsequently a follow-up large trial in adults, the PROWESS-SHOCK study, was published in 2012 and found no mortality benefit. Ultimately these findings led to removal of the drug from the market.^{35,189}

Additional supportive measures such as prophylactic low-dose heparin are used by some clinicians.²³⁹ Many investigators have studied the effect of heparin on survival and disseminated intravascular coagulation in patients with meningococcemia, and no consistent beneficial effect on these parameters has been noted. Serious side effects directly attributed to heparin therapy have been reported rarely.⁸⁹ The difficulty in adjusting the dose in small infants may lead to heparin intoxication. A retrospective chart review of 24 patients with purpura fulminans showed less necrosis of the digits and extremities in patients treated with heparin, but the results were not statistically significant.¹³⁴ A randomized, placebo-controlled trial evaluated the use of continuous heparin in patients with sepsis and found no benefit on 28-day mortality or length of stay.¹¹⁹

Other experimental therapies have been attempted in patients with fulminant meningococcemia. Anecdotal reports or small case series describe use of tissue plasminogen activator,^{2,160} antithrombin III infusion,⁵² topical nitroglycerin,^{115,154} plasmapheresis,⁵⁰ and extracorporeal membrane oxygenation (ECMO).¹³⁶ Continuous caudal block has been used to restore lower extremity perfusion.²¹⁹ Insufficient evidence exists to say that any of these therapies have a significant impact on outcomes in meningococcal disease. Larger, multicenter studies are needed to evaluate efficacy.

CONTROL AND PREVENTION

Chemoprophylaxis

The mode of transmission of *N. meningitidis* is direct contact with respiratory droplets or secretions. The ability of it to spread from person to person and cause epidemic disease has been recognized since the 1800s. Chemoprophylaxis is recommended for individuals with close contact to cases with invasive disease if the contact occurred in the 7 days preceding onset of illness in the case. Candidates for prophylaxis include household members, child-care center contacts, and persons with direct exposure to oral secretions.⁵⁵ The secondary attack rate in households with an index case is approximately 1000 times the attack rate in the general population.^{7,209} Household crowding and young age are factors that increase the secondary attack rate. For close contacts, chemoprophylaxis is recommended regardless of immunization status.⁵ Additionally airline passengers who had direct contact with respiratory secretions or who were seated directly next to an index case during a flight lasting 8 hours or longer should receive chemoprophylaxis.⁵

Several epidemiologic studies suggest that casual acquaintances (e.g., school-aged classmates) are not at increased risk, although some authors report secondary cases in this population.^{117,121} Therefore casual acquaintances are not candidates for chemoprophylaxis. Additionally contact with individuals who have *N. meningitidis* isolated from nonsterile sites, such as respiratory secretions, would not qualify for chemoprophylaxis.⁵⁵ Mass prophylaxis is not recommended to control large outbreaks; instead vaccine is used in this setting.⁵⁵

The period of communicability of the index patient is not well established. Most public health authorities recommend that persons in contact with the patient up to 7 days before onset of illness be considered for prophylaxis. Prophylaxis should be instituted as soon as possible, ideally within 24 hours, after identification of the index case.⁵⁵ It is not necessary to wait for laboratory confirmation of a case if the clinical picture is most consistent with meningococcal infection. Nasopharyngeal cultures are not recommended as they can delay therapy.⁵⁵ Secondary cases originally were defined as occurring more than 24 hours but less than 31 days after onset in the index case.⁴² Approximately 70% of

TABLE 88.1 Chemoprophylaxis Regimens for Eradication of *Neisseria Meningitidis*

Drug	Age	Dose/Duration
Rifampin ^a	Children <1 mo	5 mg/kg/dose PO twice daily for 2 days (4 doses)
	Children ≥1 mo	10 mg/kg/dose (maximum dose 600 mg) PO twice daily for 2 days (4 doses)
	Adults	600 mg dose PO twice daily for 2 days (4 doses)
Ceftriaxone	Children <15 y	125 mg IM, single dose
	Children ≥15 y and adults	250 mg IM, single dose
Ciprofloxacin ^b	Children	Not recommended
	Adults	500 mg PO, single dose
Azithromycin ^c	Children	10 mg/kg PO (maximum dose 500 mg), single dose
	Adults	500 mg PO, single dose

IM, Intramuscularly; PO, orally.

^aRifampin is not recommended for pregnant women (teratogenicity in laboratory animals). The reliability of oral contraceptives may be affected by rifampin therapy; therefore alternative contraceptive measures should be used during and for the month after rifampin administration.

^bCiprofloxacin is not recommended in children, pregnant women, or lactating women.

Ciprofloxacin can be used in children if there is no acceptable alternative.

^cAzithromycin is *not* routinely recommended and is not listed in the US Centers for Disease Control recommendations for prophylaxis.

secondary cases will occur in the first 7 days after presentation of the index case.⁴²

In the hospital setting, other preventative measures should be pursued. Droplet precautions should be continued for 24 hours after initiation of appropriate antibiotics in the hospitalized patient. The index patient should receive chemoprophylaxis before discharge unless he or she has been treated with ceftriaxone. A single dose of ceftriaxone is sufficient to eradicate nasopharyngeal colonization.⁵ Abramson and Spika¹ reported that four of 14 (29%) patients with meningococcal infection treated with intravenous penicillin had positive culture results from the respiratory tract 1 week after completion of therapy. The original drug used for chemoprophylaxis was sulfadiazine. However, a large percentage of strains now are resistant to sulfa. Table 88.1 lists four antibiotics that are highly effective in eradicating meningococcus from the nasopharynx. Rifampin is generally the drug of choice for chemoprophylaxis of children. It is generally well tolerated but has side effects, including orange urine and sweat, orange staining of contact lenses, and stimulation of liver microsomal enzymes leading to reduction in levels of other concurrent medications (e.g., oral contraceptives, anticoagulants, digoxin, and phenytoin). Development of resistant strains has been reported rarely.⁵⁷ Rifampin, ciprofloxacin, and ceftriaxone have been evaluated in a randomized, comparative study.⁵⁹ All three drugs are highly effective, eradicating carriage in 90% to 95% of individuals.⁵⁴ Ceftriaxone is the drug of choice for a pregnant contact and also should be considered for children because a single intramuscular injection may result in greater compliance than four doses of rifampin. A single oral dose of ciprofloxacin is highly effective in eradicating carriage of meningococcus, but it is less desirable in individuals younger than 18 years because fluoroquinolones tend to be reserved to select circumstances in children. In addition, a 2009 article reported four cases of invasive meningococcal disease in the United States with isolates resistant to ciprofloxacin, although this remains rare.^{55,244}

Although not recommended as a first-line agent, azithromycin was studied in a randomized, controlled trial comparing 500 mg of azithromycin orally once to rifampin 600 mg orally twice daily for 2 days. Carriage was eradicated in 56 of 60 (93%) colonized adults treated with azithromycin compared to eradication in 95% of the 59 colonized adults

treated with rifampin.⁹² Azithromycin is a consideration in areas where ciprofloxacin resistance has been detected.⁴²

As mentioned in the next section, secondary disease can also be prevented by immunization of contacts, which is the preferred intervention for large outbreaks.⁴² The single most important element of chemoprophylaxis is education regarding the need for immediate medical attention if contacts develop signs or symptoms of a febrile illness. No prophylactic strategy is 100% effective, and ill contacts should be medically evaluated with a high suspicion for meningococcal disease.

Outbreaks

A meningococcal outbreak is defined as three or more confirmed or probable primary cases within a three month period.⁴² Between 1994 and 2002, there were 69 outbreaks of meningococcal disease in the United States.¹⁷¹ Of these, 43 were due to serogroup C.⁹⁰ Outbreak-associated cases represented less than 2% of total cases of invasive disease, but they were associated with a higher case fatality rate than sporadic cases (21% vs. 11%; odds ratio, 3.3; 95% confidence interval [CI], 2.0–5.5).³⁰

Meningococcal vaccines, described in detail later, are crucial in control of large meningococcal outbreaks. Internationally meningococcal vaccines have been used to control epidemics for several decades.¹⁷¹ Reasons to not use chemoprophylaxis in large outbreaks include cost, concern for emergence of drug resistance, and difficulty in assuring simultaneous administration of drug in many individuals.⁴² Vaccination for a population at risk (within an institution or a geographic setting) should be considered when the primary attack rate is more than 10 cases per 100,000 persons.^{42,55} Usually vaccine candidates are those younger than 30 years within the population at risk in a community outbreak or all persons at risk in an organization-based outbreak.⁵⁵ The outbreak serogroup dictates the candidate vaccine.

Outbreaks in the past few decades have been defined geographically, while others have affected individuals with common risk factors. For example, in the mid-1990s an outbreak of serogroup B disease occurred in Oregon that resulted in a peak incidence of 4.5 cases per 100,000 individuals.¹⁷¹ Although the rate in Oregon has since decreased, meningococcal disease continues to be hyperendemic in the state. Other examples include outbreaks in illicit drug users and men who have sex with men in New York.¹³⁰

There were seven serogroup B college outbreaks between 2009 and 2015 that resulted in 41 cases and 3 deaths.¹⁴⁶ In 2013, two unrelated outbreaks in college campuses (Princeton and University of California-Santa Barbara) due to serogroup B were contained with use of MenB-4C vaccine, which is now licensed by the US Food and Drug Administration (FDA) but was dispensed at the time under an Investigational New Drug designation.⁵⁴ At Princeton, 95% of students received at least one dose of vaccine starting in December 2013, and no further cases were identified after introduction of the vaccine.¹⁷¹ Additionally MenB-FHbp vaccine was used in a 2015 University of Oregon outbreak.¹⁷¹

Meningococcal Vaccines

Primary prevention of meningococcal disease is essential for several reasons. The presentation may be fulminant, with no opportunity for antibiotics to influence the course of the disease. Antibiotic-resistant strains now are recognized, and chemoprophylaxis of contacts is a cumbersome and often ineffective public health measure. Mass immunization offers the opportunity to prevent both endemic and epidemic disease worldwide.

Three types of vaccines, meningococcal polysaccharide vaccine (MSPV4), meningococcal conjugate vaccine (MCV), and recombinant meningococcal B vaccines are currently licensed in many countries around the world for prevention of meningococcal disease. There is no licensed vaccine for serogroup X.⁹⁰ Although more costly, meningococcal conjugate vaccines are superior to polysaccharide vaccines in several ways. Children younger than 2 years do not produce high levels of antibody in response to pure polysaccharide antigens. Polysaccharide antigens do not induce T-cell-dependent immunity with memory cell production. Polysaccharide vaccines have little effect on nasopharyngeal carriage.¹⁵¹ Last, repeated boosting with MSPV4 has resulted in a blunting of antibody response, termed *hyporesponsiveness*.^{26,144} In contrast, licensed conjugate vaccines have been shown to be immunogenic when used in

an appropriate series with boosters, even in infants.¹⁶⁷ Conjugate vaccines produce stimulation of both T-cell and B-cell-dependent immunity and have been shown to decrease nasopharyngeal carriage.⁴² For these reasons, although meningococcal polysaccharide vaccines are licensed and available in many countries, meningococcal conjugate vaccines have significant advantages.

Previously MenB vaccine development had been problematic because group B capsular polysaccharide is poorly immunogenic due its similarities to human fetal neural cell adhesion molecule. Additionally similarities to neural tissue raised concerns for induction of autoimmunity. In a few countries, including New Zealand, Norway, and Cuba, serogroup B vaccines had been developed utilizing outer membrane vesicle (OMV) in order to control epidemics. However, OMV vaccines are limited in that they are only serosubtype specific. Researchers would later capitalize on the New Zealand vaccine and create MenB-4C by adding three protein antigens (factor H-binding protein [fHbp], neisserial adhesion A [NadA], and neisserial heparin-binding antigen [NHBA]) to the New Zealand outbreak vaccine. MenB-FHbp (Trumenba) contains fHbp from the two subfamilies of this outer membrane protein providing broad serogroup B coverage.¹⁵¹

MenB-4C and MenB-FHbp have been shown to be immunogenic, and MenB-4C has been shown to have a modest impact on carriage, although efficacy is difficult to demonstrate due to rarity of meningococcal disease.¹⁵¹ A large multicountry European study examined the immunogenicity and reactogenicity of MenB-4C in 1885 infants. The vaccine was highly immunogenic against two of the three meningococcal strains tested. For the third strain, 79% of infants developed sufficient antibody response that would be considered protective. Injection site pain and fever were relatively common after vaccination.⁹⁵ A study in more than 1600 Chilean adolescents showed that a two-dose series of MenB-4C performed better than a single dose in terms of good immunogenicity that lasted at least 6 months.²⁰²

Because MenB vaccines contain antigens among non-B meningococci, MenB vaccines have the potential to provide cross-protection against other capsular groups, as supported by in vitro studies.^{135,151} However, the duration of long-term protection with these vaccines is not known.²⁰⁸

Meningococcal Vaccines in the United States

Meningococcal polysaccharide vaccine. Meningococcal polysaccharide vaccine (MPSV4, Menomune) is a capsular polysaccharide vaccine that targets serogroups A, C, Y, and W-135 and is licensed for use in individuals older than 2 years of age who are at increased risk for meningococcal disease. This vaccine was licensed in 1981 and was the only meningococcal vaccine widely available in the United States until the licensing of meningococcal conjugate vaccines. Conjugate vaccines are generally preferred over meningococcal polysaccharide vaccines in people for whom conjugate vaccines are licensed due to inferior efficacy of polysaccharide vaccines, as previously described.¹⁵¹ Additionally, although MSPV4 is the only vaccine licensed in persons older than 55 years, off-label use of conjugate vaccine is recommended in persons older than 55 years if ongoing risk in the future is anticipated. MSPV4 is given subcutaneously as a single dose.

Meningococcal conjugate vaccines. Three meningococcal conjugate vaccines are currently licensed in the United States: MenACWY-D (Menactra), MenACWY-CRM (Menveo), and HibMenCY-TT (Men-Hibrix). Quadrivalent vaccines were first licensed in the United States in 2005.⁵⁴ MenACWY-D and MenACWY-CRM are quadrivalent vaccines that couple polysaccharide capsular antigens (i.e., serogroups A, C, Y, and W-135) to a protein carrier. In MenACWY-D, the protein carrier is diphtheria toxoid and in MenACWY-CRM, the protein carrier is CRM₁₉₇ (mutant diphtheria toxin). MenHibrix is a combination *H. influenzae* type b and bivalent meningococcal conjugate vaccine (i.e., serogroups C and Y) licensed in the United States for young children aged 6 weeks to 18 months.

MenACWY-D, MenACWY-CRM, and HibMenCY-TT vaccines have been found to be safe and immunogenic in infants, children, adolescents, and adults.^{12,20,85,102,125,167,175,223} Efficacy was inferred by the demonstration of development of serum bactericidal antibodies to each of the meningococcal antigens the vaccines contain at a level that was noninferior to the response generated by polysaccharide vaccines.^{20,214}

Close monitoring for potential adverse events initially suggested a possible association between MenACWY-D (Menactra) and Guillain-Barré syndrome based on case reports through the Vaccine Adverse Event Reporting System (VAERS) shortly after the licensure of MenACWY-D.¹⁰ Subsequently the results of two large observational studies (collectively representing 2 million doses of vaccine) found no risk for Guillain-Barré associated with meningococcal conjugate vaccine.¹ Language about Guillain-Barré was removed from the meningococcal vaccine information statement.

Meningococcal conjugate vaccines are administered intramuscularly (as opposed to MPSV4, which is administered subcutaneously). Soon after licensure of meningococcal conjugate vaccines, numerous cases of misadministration of MenACWY-D (Menactra) were reported. The CDC studied 100 such cases and found that misadministration of MenACWY-D by the subcutaneous route still resulted in a protective immune response. While this route of administration is not recommended, persons who received the vaccine by this route do not need to be revaccinated.⁴¹

The duration of protection of quadrivalent meningococcal vaccination was originally thought likely to persist for 10 years. This was part of the rationale to incorporate meningococcal conjugate vaccine into the United States preadolescent vaccine platform. It was presumed that by vaccinating 11- to 12-year-old children, antibody levels would be sufficient for protection through the early college years, when there is increased risk for meningococcal disease. Subsequent studies showed significant decline in meningococcal antibody (vaccine serogroups) in adolescents 3 to 5 years after vaccination. Additionally a limited number of cases of meningococcal C or Y disease were reported to the CDC in previously vaccinated teenagers. The average time between vaccination and meningococcal disease was 3.25 years.²³² In 2010, as a result of concerns that adolescents may not be protected against invasive meningococcal disease for more than 5 years, the CDC's Advisory Committee on Immunization Practices (ACIP) recommended a booster dose of quadrivalent meningococcal vaccine be administered at age 16 years (Table 88.2).⁵⁴

Meningococcal conjugate vaccines are currently licensed in the United States for persons as young as 6 weeks through 55 years. MenACWY-CRM is licensed in persons age 2 months through 55 years; MenACWY-D is licensed in persons 9 months through 55 years; HibMenCY-TT is licensed in infants and children 6 weeks through 18 months of age. As in adolescents, waning antibody has been detected 3 to 5 years after primary immunization and is the basis for the current recommendations for boosters if an ongoing risk factor exists for meningococcal disease.⁵⁴

In the United States, the incidence of invasive meningococcal infections is highest in infants. Surveillance data from 2006 to 2012 suggest that vaccination to protect infants from meningococcal serogroups B, C, and Y by 4 months of age would prevent 63% of infections in infants.¹⁴⁵

However, because there would be a large subset of infants who would remain vulnerable to infection prior to being able to receive the two or three doses of necessary vaccine, alternate vaccination strategies could include maternal vaccination and the reduction of colonization in adolescents who serve as a reservoir of infection.¹⁴⁵

Recombinant MenB vaccines. There are two licensed recombinant serogroup B vaccines, MenB-FHbp (Trumenba) and MenB-4C (Bexsero). In 2014, MenB-FHbp (Trumenba) became the first serogroup B vaccine licensed in the United States. This was followed shortly by MenB-4C (Bexsero) in 2015.⁸⁴ MenB vaccines in the United States are licensed for individuals 10 to 25 years of age.⁵⁴ Currently MenB vaccines are recommended for high-risk individuals and can be considered for routine vaccination in adolescents.

US recommendations for use of meningococcal vaccines. Tables 88.2 to 88.6 summarize the ACIP recommendations for the use of vaccines to prevent meningococcal disease.^{4,55,113,126,194} Quadrivalent meningococcal vaccine is recommended for all US children (who have no contraindication) at the 11- to 12-year-old preadolescent visit, with a booster dose at age 16 years. The booster is recommended because vaccine efficacy wanes by up to 60% 2 to 5 years after vaccination.⁵⁴ Teenagers who receive their primary dose of quadrivalent meningococcal conjugate vaccine at 13 to 15 years should receive a booster at 16 to 18 years. If the primary dose of meningococcal conjugate vaccine is given on or after the 16th birthday, no booster is recommended. In the 2016 vaccine schedule, meningococcal B vaccine is offered as a consideration for any adolescent 16 to 23 years of age.^{6,194} Meningococcal vaccines are also recommended in other scenarios including (1) underlying condition that predisposes to developing invasive meningococcal infection (complement component deficiencies and persons with functional or anatomic asplenia), (2) travel or residence in regions with endemic disease, (3) in the setting of outbreaks, and (4) for microbiologists who routinely work with *Neisseria meningitidis*. Recommendations for vaccines in these groups are listed in Tables 88.3 to 88.6. Of note, when vaccinating for travel to the meningitis belt or the Hajj it is necessary to administer quadrivalent meningococcal vaccine in order to immunize against MenA.⁵⁴

Meningococcal Vaccines Outside the United States

Meningococcal A vaccine. The story of development and delivery of a conjugate serogroup A meningococcal vaccine to Africa is an inspirational public health achievement. In 2001, a partnership was developed between the World Health Organization (WHO) and the Program for Appropriate Technology in Health (PATH) around the Meningitis Vaccine Project. This project was funded by the Bill and Melinda Gates Foundation, and its goal was to develop and introduce an affordable meningococcal conjugate serogroup A vaccine in Africa. The vaccine was developed with help from additional agencies at a cost of \$0.40 per dose. Two

TABLE 88.2 Recommendations for Adolescent Meningococcal Vaccination

Targeted Serogroup	Age	Primary Series	Booster Recommendations
A, C, W, Y	Age 11–18 y (preferably at age 11 or 12 y), routinely	Give one dose ^a of MCV4 ^b	Booster at age 16 y if primary dose given at age 12 y or younger Booster at 16–18 y if primary dose given at 13–15 y ^c No booster if primary dose given at ≥16 y
	Age 19–21 y, first-year college students living in residence halls	Give one dose ^a of MCV4 if person has not received a dose on or after 16th birthday	No booster, unless other risk factors
B ^d	Age 16–23 y (preferred 16–18 y)	Give two doses of MenB-4C (Bexsero), 1 mo apart or Give three doses of MenB-FHbp (Trumenba) at 0, 2, and 6 mo, or give 2 doses at 0 and 6 mo	No booster

^aIf the person is HIV-positive, give a two-dose primary series, 8 weeks apart.

^bMCV4, Menveo or Menactra.

^cThe minimum interval between doses of MCV4 is 8 weeks.

^dVaccination against serogroup B is not routinely recommended but can be considered.

Data from references 6, 126, 194.

TABLE 88.3 Recommendations for Meningococcal Vaccination in Individuals With Underlying Conditions (Persistent Complement Component Deficiencies^a or Persons With Functional or Anatomic Asplenia)

Targeted Serogroup	Age of First Meningococcal Vaccination	Primary Series	Booster Recommendations
A, C, W, Y	Age 2–6 mo	Give four doses of MenACWY-CRM (Menveo) at 2, 4, 6, and 12 mo	See booster for age 2–55 y
	Age 7–23 mo	Give two doses of MenACWY-CRM (Menveo) (if age 7–23 mo) ^c or MenACWY-D (Menactra) (if age 9–23 mo with complement deficiency ONLY) ^d , 12 wk apart	See booster for age 2–55 y
	Age 2–55 y	Give two doses of MCV4, ^{b,d} 8 wk apart	If primary series at: 2 mo–6 y: booster 3 y after primary series, then every 5 y thereafter ≥7 y: Booster every 5 y
	Age ≥56 y	Give two doses of MCV4, ^{b,e} 8 wk apart	Boost every 5 y with MCV4
C, Y	Age 2–11 mo	Give four doses of Hib-MenCY (MenHibrix) at ages 2, 4, 6, and 12–15 mo	No booster for Hib-MenCY (MenHibrix)
	Age 12–18 mo	Give two doses Hib-MenCY (MenHibrix), 8 wk apart	No booster for Hib-MenCY (MenHibrix)
B	Age ≥10 y ^f	Give two doses of MenB-4C (Bexsero), 1 mo apart or Give three doses of MenB-FHbp (Trumenba) at 0, 2, and 6 mo	No booster for MenB

^aPersistent complement component deficiencies include C3, C5-C9, properdin, factor H, and factor D.

^bMCV4, Menveo or Menactra.

^cMenACWY-CRM (Menveo) second dose should be after first birthday.

^dChildren with functional or anatomic asplenia should complete a series of PCV13 vaccine before vaccination with MCV4; if MenACWY-D (Menactra) is to be given, begin at age 2 years and administer meningococcal vaccination at least 4 weeks after the fourth dose of pneumococcal conjugate vaccine to avoid possible interference with immune response to the pneumococcal vaccine series.

^eMCV4 is preferred for those 56 years of age or older who have previously received MCV4 or for whom multiple doses are anticipated, as would be the case for someone with an underlying condition. MPSV4 is recommended for those ≥56 years who have not previously received MCV4 and for whom only one dose is anticipated.

^fApproved for those aged 10–25 years but recommended for ≥10 years.

Data from references 55, 126, 194.

TABLE 88.4 Recommendations for Meningococcal Vaccinations for Travel (Travelers to or Persons Residing in Countries Where Meningococcal Disease Is Endemic or Hyperendemic)

Targeted Serogroup	Age of First Meningococcal Vaccination	Primary Series	Booster Recommendations
A, C, W, Y	Age 2–6 mo	Give four doses ^a of MenACWY-CRM (Menveo) at 2, 4, 6, and 12 mo	See booster for age 2–55 y
	Age 7–23 mo	Give two doses ^{a,c} of MenACWY-CRM (Menveo) (if age 7–23 mo) or MenACWY-D (Menactra) (if age 9–23 mo), 12 wk apart	
	Age 2–55 y	Give one dose of MCV4 ^b	If risk continues and primary series at: 2 mo–6 y: booster 3 y after primary series, then every 5 y thereafter ≥7 y: booster every 5 y
	Age ≥56 y	Give one dose of MCV4 or MPSV4 (Menomune) ^d	If risk continues: boost every 5 y with MCV4
B	All ages	Not recommended	

^aCompletion of the entire series is preferred before travel.

^bMCV4, Menveo or Menactra.

^cIf a child aged 7–23 months will enter endemic area in less than 3 months, give doses as soon as 2 months apart.

^dMCV4 is preferred for those aged ≥56 years who have previously received MCV4 or for whom multiple doses are anticipated. MPSV4 is recommended for those aged ≥56 years who have not previously received MCV4 and for whom only one dose is anticipated.

Data from references 4, 126, 194.

studies (one in children 12 to 23 months of age and one in persons 2 to 29 years of age) showed the vaccine to be more immunogenic than and with a similar safety profile to the polysaccharide serogroup A vaccine.²⁰⁷ Burkina Faso became the first country to conduct a nationwide rollout of the meningococcal conjugate serogroup A vaccine (MenAfriVac) nationwide. More than 11 million people aged 1 to 29 years were immunized in a 10-day period in December 2010. During the subsequent 2011 winter dry season only 2665 suspected meningococcal cases were reported (80% reduction over prior years). From the suspect cases, 1437 specimens were cultured (or submitted for PCR), and only four isolates were identified to be serogroup A—all from unvaccinated individuals.⁵¹ Carriage studies done before and after vaccine implementation in Burkina Faso show a decrease in oropharyngeal carriage. Before

vaccine implementation, examination of 20,326 oropharyngeal cultures yielded a carriage rate of 0.4%. Fifteen thousand oropharyngeal samples obtained after the MenAfriVac implementation program revealed none of the samples was positive for serogroup A *N. meningitidis*.^{48,132} More than 55 million Africans have now been vaccinated in at least six countries. Large-scale institution of this vaccine has dramatically decreased the incidence of serogroup A meningococcal disease.¹⁷¹

Meningococcal B vaccines. Tailor-made Men-B vaccines using serogroup B outer membrane proteins were developed for outbreaks that began in the 1970s in Norway and Cuba and in the 1990s in New Zealand.¹⁷¹ In addition to the United States, MenB-4C (Bexsero) is licensed in Europe and Australia.^{3,135} In the United Kingdom, MenB-4C has been offered as part of the routine vaccination program since September 2015.¹³⁵

Meningococcal C vaccines. Meningococcal C conjugate vaccination in the United Kingdom has been effective^{187,220} and has produced herd immunity (67% disease reduction in unvaccinated 1- to 17-year-olds)¹⁸⁸ and a 66% reduction in adolescent nasopharyngeal carriage. A meningococcal serogroup C conjugate vaccine program was begun in the United Kingdom in 1999 with a 2-, 3-, 4-month primary series schedule for infants. Children 1 to 18 years of age received a single dose of meningococcal serogroup C conjugate vaccine (MCCV). In 2002, MCCV was offered to all individuals up to age 25 years. Later studies from the United Kingdom showed rapid waning of immunity in vaccinated infants (vaccinated at 2, 3, and 4 months). Despite high vaccine efficacy during the first year after immunization, vaccine efficacy fell significantly at 1 year or more after vaccination.³⁴ As of 2013, the vaccine schedule was changed to a single infant vaccine at 4 months, with two boosters at 12 months and 14 years of age, respectively.³

The United Kingdom's meningococcal conjugate serogroup C program has been highly effective in producing a dramatic and sustained reduction in serogroup C disease. The overall incidence rate of serogroup C disease has fallen by 98.7% in England and Wales, and no evidence exists for serogroup replacement.^{33,148}

Several other countries also incorporated meningococcal C conjugate vaccines into their immunization programs because of circulating clonal serogroup C strains. Canada's staggered serogroup C vaccine implementation program allowed for a comparison of the meningococcal disease incidence in provinces with and without vaccine implementation; provinces with vaccine implementation showed substantial reduction in meningococcal C disease, and no serogroup replacement was seen.¹⁹

Future for Meningococcal Vaccines

A deeper understanding of the pathophysiologic mechanism of meningococcal disease and the bacterial structures critical for antigenicity and immunogenicity in humans is needed. A safe and effective vaccine that could induce protection against all encapsulated meningococci in all age groups is the ultimate goal.

Acknowledgments

TABLE 88.5 Recommendations for Meningococcal Vaccinations for Outbreaks (Persons in a Defined Risk Group During an Institutional or Community Outbreak^a)

Targeted Serogroup	Age of First Meningococcal Vaccination	Vaccine
A, C, W, Y	Age 2–6 mo	Give 4 doses of MenACWY-CRM (Menveo) at 2, 4, 6, and 12 mo
	Age 7–23 mo	Give 2 doses of MenACWY-CRM (Menveo) (if age 7–23 mo) ^c or MenACWY-D (Menactra) (if age 9–23 mo), 12 wk apart
	Age 2–55 y	Give 1 dose of MCV4 ^b
	Age ≥56 y	Give 1 dose of MCV4 ^b or MPSV4 (Menomune) ^d
C, Y	Age 2–11 mo	Give 4 doses of Hib-MenCY (MenHibrix) at ages 2, 4, 6, and 12–15 mo
	Age 12–18 mo	Give 2 doses Hib-MenCY (MenHibrix), 8 wk apart
B	Age ≥10 y	Give 2 doses of MenB-4C (Bexsero), 1 mo apart or Give 3 doses of MenB-FHbp (Trumenba) at 0, 2, and 6 mo

^aSeek advice of local public health authorities to determine if vaccination is recommended.

^bMCV4, Menveo or Menactra.

^cMenACWY-CRM (Menveo) second dose should be after first birthday.

^dMCV4 is preferred for those aged ≥56 years who have previously received MCV4 or for whom multiple doses are anticipated. MPSV4 is recommended for those aged ≥56 years who have not previously received MCV4 and for whom only one dose is anticipated.

Data from references 126, 194.

TABLE 88.6 Recommendations for Meningococcal Vaccinations for Microbiologists (Microbiologists Routinely Working With *Neisseria Meningitidis*)

Targeted Serogroup	Age	Primary Series	Booster Recommendations
A, C, W, Y	Age 19–55 y	Give 1 dose of MCV4 ^a	If risk continues, boost every 5 y with MCV4
	Age ≥56 y	Give 1 dose of MCV4 or MPSV4 (Menomune) ^b	If risk continues, boost every 5 y with MCV4
B	Age ≥19 y	Give 2 doses of MenB-4C (Bexsero), 1 mo apart	No booster
		or Give 3 doses of MenB-FHbp (Trumenba) at 0, 2, and 6 mo	

^aMCV4, Menveo or Menactra.

^bMCV4 is preferred for those aged ≥56 years who have previously received MCV4 or for whom multiple doses are anticipated. MPSV4 is recommended for those aged ≥56 years who have not previously received MCV4 and for whom only 1 dose is anticipated.

Gonococcal Infections

Charles R. Woods Jr

Gonorrhea, the foremost manifestation of human disease caused by *Neisseria gonorrhoeae* (the gonococcus), is one of the oldest known human diseases. Gonorrhea has been known as “the clap” since the late 1300s. This term may have derived from the Les Clapier district of Paris, where prostitutes were housed during the Middle Ages.^{131,182}

The description by Neisser of *N. gonorrhoeae* in stained smears of urethral and other exudates in 1879 and culture of the organism by Leistikow and Löffler in 1882 provided the foundation for modern understanding of the clinical spectrum of gonococcal diseases. The advent of safe and effective antimicrobial agents, first sulfonamides in 1936 and then penicillin in 1943, was the next major advance in combating gonorrhea.^{182,131} Modern knowledge of the molecular pathogenesis of *N. gonorrhoeae* infection began in 1963 with the observation by Kellogg and colleagues¹⁸⁶ that gonococcal strains with differences in colony morphology also varied in virulence. Further understanding of the clinical aspects of the disease was facilitated by development of the Thayer-Martin medium in 1964.³²²

N. gonorrhoeae remains a major international public health problem because of reproductive sequelae of infection (e.g., infertility), the ever-growing resistance to antimicrobial agents, and disproportionate case burdens in public clinics.^{54,62,184,209,210,265} Efforts to develop an effective vaccine are ongoing.^{50,345} Additional information on gonococcal infections is provided in Chapter 42.

EPIDEMIOLOGY

Gonococcal infections remain second in incidence only to *Chlamydia* infections among reportable diseases in the United States.^{55,62} The United States reached a historic nadir of 98.1 cases per 100,000 population in 2009, but rates have subsequently increased to 110.7 in 2014.⁶² Regions with higher rates of adult disease have higher numbers of pediatric cases,^{99,122} a finding that reflects the adult origin of virtually all pediatric cases. (For the most current national data for the United States, see the

Gonococcal Isolate Surveillance Project [GISP] website: <http://www.cdc.gov/std/gisp/default.htm>.)

An estimated 820,000 new cases of gonococcal infection occur annually in the United States.³⁴³ At least half of the cases are thought to go undiagnosed or unreported. In 2014 in the United States, 350,062 cases were reported.⁶² US national trends in reported rates are shown in Fig. 89.1. Rates of gonorrhea are based primarily on detection of symptomatic infection. Asymptomatic chronic infection in adults is well documented and may account for 5% of cases.¹⁶⁶ Such infections can be transmitted. Some untreated cases will resolve over time. Data also indicate that asymptomatic infection occurs in children, including prepubertal children.^{3,115,153,166} Gonococcal infections rarely are fatal (approximately four deaths per year in the United States), with death being caused by gonococcal sepsis.^{55,210}

Gonorrhea rates remain highest among adolescents and young adults (Fig. 89.2). In 2014, rates of reported cases were 430.5 of 100,000 and 221.1 among adolescent females and males 15 to 19 years of age, respectively, and 533.7 and 485.6 among females and males 20 to 24 years of age, respectively.⁶² Rates among African Americans were 10.6 times higher than among whites, which represents a decline from 18.7 in 2010.^{60,62} Low socioeconomic status, early onset of sexual activity, unmarried marital status, and past gonococcal infections are risk factors for acquiring gonococcal infection, as are prostitution and illicit drug use.^{15,37} Limited access to health care also may contribute to increased prevalence of disease in impoverished populations.⁵⁷ The prevalence of gonococcal infection in adolescents attending private clinics probably is lower than that in those seeking care in publicly funded settings.²¹ For women, the use of hormonal contraceptives may increase the risk for acquiring infection, whereas the use of spermicides or diaphragms appears to be at least partially protective.^{206,207}

FIG. 89.1 Rates of gonorrhea in the United States, 1941–2014. After steady decline from 1975 through 1997, overall gonorrhea rates have plateaued, reaching a historic nadir of 98.1 cases per 100,000 population in 2009. The rate in 2014 was 110.7. Gonorrhea is substantially underdiagnosed and underreported. (From Centers for Disease Control and Prevention: <http://www.cdc.gov/std/stats14/figures/12.htm>. For the most currently available data, see <http://www.cdc.gov/std/gisp/default.htm>.)

FIG. 89.2 Rates of gonorrhea by age and sex: United States, 2014. This pattern has been the same for decades. Rates in males may be underreported compared to females. (From Centers for Disease Control and Prevention: <http://www.cdc.gov/std/stats14/figures/17.htm>. For the most currently available data, see <http://www.cdc.gov/std/gisp/default.htm>.)

Among persons seeking care in clinics participating in the STD Surveillance Network, rates of gonococcal infection among men who have sex with men (MSM) are higher than those among men who have sex only with women (MSW) and among women, especially among adolescent MSM 19 years of age or younger.⁶²

The southeastern United States continues to have rates of gonorrhea higher than those of other regions of the country. In 2014, rates in the South, Midwest, West, and North were 131.4, 106.6, 101.1, and 84.7 cases per 100,000 population, respectively.⁶² About 50% of reported cases occurred in only 70 counties or independent cities in the United States in 2014 (Fig. 89.3). Humans are the only reservoir of *N. gonorrhoeae*. Exudate and secretions from infected mucosal surfaces allow transmission to occur during the intimate contact of sexual acts, parturition, and, rarely, household exposure. The incubation period usually is 2 to 7 days. No evidence of airborne transmission of gonococci exists; contact with viable microbes is required for transmission. Gonococci survive on surfaces outside the human body for only short periods (probably minutes). Although organisms can be cultured from environmental sources (e.g., toilet seats) for up to 3 hours after artificial inoculation in large numbers, viable gonococci have not been recovered from random samplings in public restrooms.¹²⁵

Nonsexual transmission of *N. gonorrhoeae* to the genitalia, rectum, or oropharynx of children rarely occurs and never should be presumed without extensive investigation of the social setting of the infected child.²³⁶ Childhood infection potentially could be acquired when a child cosleeps in the same bed with an infected family member,¹²⁵ and sharing of bath towels and other similar objects has been suspected as the cause of epidemics in prepubescent girls living together.³⁰⁵ Although persistence of apparently perinatally acquired gonococcal infection for up to 1 year of age has been reported, and fomite or maternal nonsexual transmission to young infants is plausible,³³ these possibilities should not be generalized beyond infancy. Gonococcal conjunctivitis can be acquired nonvenereally.¹⁹⁷

The risk for males acquiring urethral infection after a single episode of vaginal intercourse with infected females is estimated to be 20%. With four exposures, the risk increases to 60% to 80%. The prevalence of infection in females named as sexual contacts of males with gonococcal urethritis has been reported to be 50% to 90%.^{159,163}

MICROBIOLOGY

Neisseria spp. are aerobic, gram-negative, nonmotile, non-spore-forming cocci that occur in pairs (diplococci), with adjacent sides flattened. They have the typical gram-negative microbial outer membrane overlying a thin peptidoglycan layer and cytoplasmic membrane. The species lacks a true polysaccharide capsule but produces a surface polyphosphate that provides a hydrophilic, negatively charged surface.²⁴² In Gram stains of clinical specimens, the microbes frequently are observed within phagocytes.³⁰⁰

Gonococci are able to use glucose, lactate, and pyruvate as carbon sources but cannot use other carbohydrates, which is the basis for the carbohydrate utilization tests for speciation of *Neisseria* (Table 89.1). Catalase and cytochrome oxidase are produced by the gonococcus, as in most *Neisseria* spp., but gonococci do not produce appreciable amounts of superoxide dismutase. Growth is optimal in a 5% carbon dioxide atmosphere at 35°C to 37°C (95°F–98.6°F) and a pH of 6.5 to 7.5. Gonococci do not survive below pH 6.0, grow poorly below 30°C (86°F), and do not survive above 40°C (104°F).

Neisseria spp. require enriched media, including free iron, to support their growth. Multiple colony types are evident when a single isolate is grown on clear agar. Small convex glistening colonies are piliated, whereas larger, flatter colonies are nonpiliated. In vitro passage usually results in loss of pili. Under low-power microscopy, some colonies appear opaque or granular and others are transparent. The former represent colonies in which most cells express one or more opacity-associated proteins (Opa), whereas in the latter colonies, most cells do not express these proteins.^{36,40,186,307,317,318,333}

Culture and Speciation From Clinical Specimens

The organisms are cultured best on chocolate blood agar in an atmosphere enriched by carbon dioxide. If the clinical specimen has been obtained

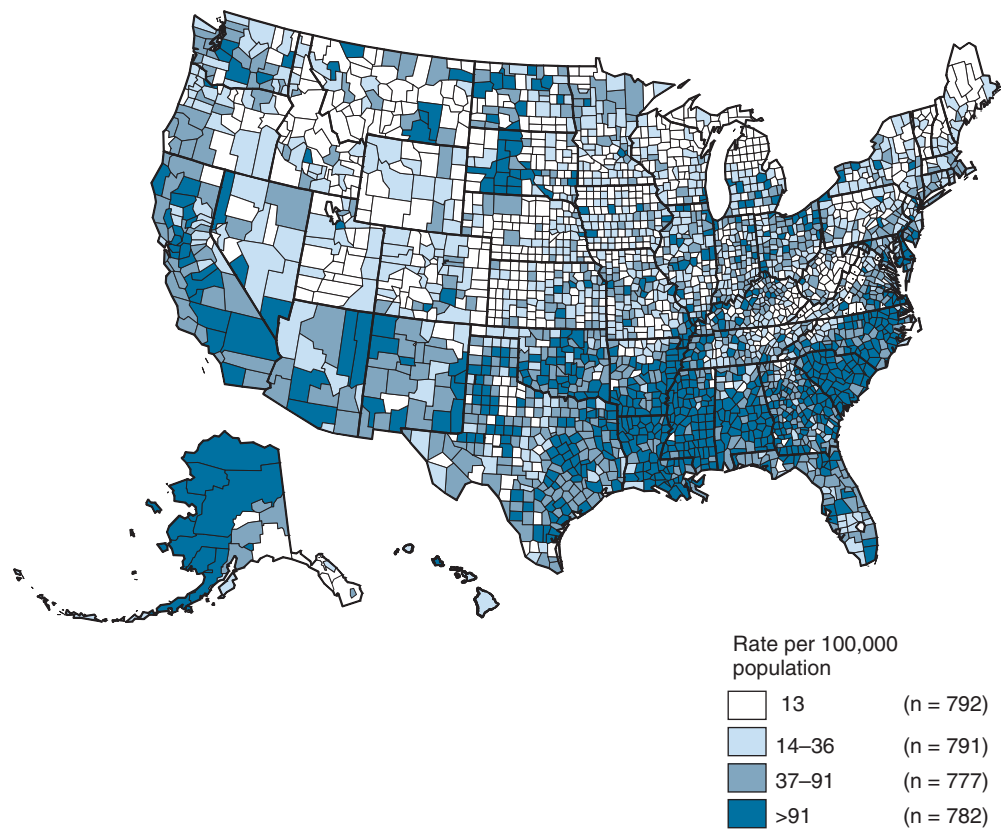

FIG. 89.3 Rates of gonorrhea by county in the United States, 2014. (From Centers for Disease Control and Prevention: <http://www.cdc.gov/std/stats14/figures/16.htm>. For the most currently available data, see <http://www.cdc.gov/std/gisp/default.htm>.)

from a highly contaminated site (e.g., rectum or cervix), a selective medium containing nystatin, vancomycin, trimethoprim, and colistin (e.g., modified Thayer-Martin medium) to suppress contaminating flora allows the growth of most *Neisseria* spp. A few strains of gonococci are inhibited by vancomycin.^{36,223} Chocolate agar without antimicrobial agents is preferred if the culture is taken from a usually sterile area such as blood, cerebrospinal fluid (CSF), synovial fluid, or a skin lesion. Gonococcal colonies usually are evident on agar plates within 24 to 48 hours after inoculation. Frequent propagation is necessary to maintain isolates because viability is lost rapidly after 48 hours of growth.

Because gonococci cannot tolerate drying, clinical specimens must be plated as soon as possible onto appropriate media. Transport bottles that contain medium and a carbon dioxide–enriched atmosphere should be used if definitive processing of the specimen must be delayed.

Transport bottles should be maintained upright to preserve the carbon dioxide atmosphere.

In addition to sugar fermentation patterns (see Table 89.1) and oxidase positivity, other biochemical reactions can be used to differentiate between *Neisseria* spp. or confirm that an isolate is *N. gonorrhoeae*.³⁴³ Enzyme substrate tests that identify the presence or absence of 1-hydroxypropylaminopeptidase, γ -glutamyl aminotransferase, and β -galactosidase are available as an adjunctive means of confirmation.⁸⁶ Gonococci possess only the former. These reactions alone will not distinguish *N. gonorrhoeae* from several commensal *Neisseria* spp. Antigen-detection–based tests, including fluorescent antibody staining, also have been used to confirm the identity of an isolate as *N. gonorrhoeae*.¹⁸⁵ Tests based on detection of gonococcal nucleic acid sequences, which are being used increasingly for diagnostic purposes, can be used

to confirm the identity of gonococcal isolates from cultures. Additional information about laboratory methods that should be used to distinguish *N. gonorrhoeae* from other *Neisseria* species is available at <http://www.cdc.gov/std/gonorrhea/lab/ident.htm>.⁶³

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) can be used to identify *N. gonorrhoeae* in clinical specimens.²⁸⁷ As databases of MALDI-TOF MS patterns of various neisserial species are expanded, misidentification of species within this genus by this method should decrease.

Genetic Characteristics

Gonococci have a circular chromosome consisting of 2219 kilobases (kb), which is about half the size of the *Escherichia coli* genome.⁹⁷ The gonococcal genome has approximately 2250 predicted open-reading frames.³⁴ The entire genomes of *N. gonorrhoeae* strains FA1090, NCCP11945, and ST1407 have been sequenced. A macrorestriction map with the positions of many genetic markers has been available since 1991.^{71,154,251} More than 1300 open-reading frame sequences have been validated.³⁴ *N. gonorrhoeae* are polyploid, with two to five genome equivalents present in each cell. These copies are ultimately haploid in that strains cannot be made to carry two different alleles at the same locus.²⁷⁶

RNA expression analyses of cervicovaginal lavage specimens collected from women recently exposed to infected male partners compared to the same isolates after growth in chemically defined medium showed that 140 genes had increased expression and 165 genes had decreased expression during natural infection.²¹¹ A large portion of the genes with increased expression are related to regulatory functions and iron scavenging.

Piliated gonococcal cells (the natural *in vivo* state) are competent for genetic transformation by exogenous DNA at all stages of growth.²⁴ Only homologous DNA is taken into the cell.¹⁰³ Gonococci are highly autolytic and release DNA in a biologically active form. Thus different strains are able to exchange genetic material readily. Such exchange can lead to further genetic and phenotypic diversity, which helps maintain the species in its human hosts and facilitates transfer of chromosomal antibiotic resistance genes.²⁸⁵

A 36-kb conjugal plasmid is present in many gonococci. It efficiently mobilizes its own transfer and other non-self-mobilizable plasmids (e.g., the 4.5- and 7.5-kb penicillinase plasmids), but not chromosomal genes.^{238,248,272} Extrachromosomal, nonplasmid DNA circles recently have been identified in wild-type gonococcal isolates. They may play a role in gene recombination, amplification of chromosomal genes, and transformation.¹⁷ Gonococci possess multiple restriction endonucleases and their corresponding DNA methylases.³¹⁶ The species is relatively nonmutagenic and lacks photoreactivation and error-prone repair systems.⁴⁶

Strain Typing

The ability to differentiate one strain from another allows investigation of the epidemiology of transmission of gonorrhea across populations and assessment of virulence factors. Numerous methods have been applied to gonococci.

Auxotyping classifies strains according to their ability to grow or not grow in the absence of 11 specific compounds, including amino acids (e.g., arginine and proline), purines, pyrimidines (e.g., hypoxanthine and uracil), and other nutrients (e.g., thiamine). Approximately 20 auxotype phenotypes are recognized. A single auxotype can represent many genotypes.²⁹⁵ The auxotype of greatest importance is designated arginine, hypoxanthine, and uracil negative (AHU⁻). Such strains are unable to grow in the absence of these compounds. AHU⁻ strains typically are more resistant to killing by normal human serum, are more likely to cause asymptomatic infections in males, and are found more frequently in patients with disseminated infection.^{107,187} AHU⁻ strains often are susceptible to vancomycin.²²³

A serologic technique based on antigenic heterogeneity of the porin protein contained in the outer membrane of the gonococcus is able to divide strains into two immunochemically distinct serogroups, PorA and PorB, with various serovars within each.^{9,162,174,188,282,283} This method is no longer used for epidemiologic evaluations.

Multiple genotyping methods have been applied to *N. gonorrhoeae*.²⁰⁴ Simple restriction endonuclease methods^{113,256} have been supplanted

by polymerase chain reaction (PCR)-based methods and pulsed-field gel electrophoresis (PFGE). *N. gonorrhoeae* multiantigen sequence typing (NG-MAST) is based on internal variation of two highly polymorphic loci and has been used for cluster identification, tracing sexual contacts, and investigating treatment failures.³²⁴ These methods appear most useful for local microepidemiologic purposes.

Multilocus sequence typing is the primary typing method used now for macroepidemiologic analyses such as monitoring global spread of clones or clonal complexes with particular virulence traits or antimicrobial resistance patterns. At least two seven-loci-based schemes have been developed.³²⁴ Whole-genome sequencing has been applied to a set of 169 isolates and grouped these into 12 clades.⁹⁵ This method may supplant all others as its associated costs decrease over time. The high ratio of recombination to mutation events, estimated at 2.2 in a recent study,¹¹² may make comparison on clonality over longer periods of time more difficult.

PATHOGENESIS

A continuously expanding body of literature is devoted to the pathogenesis of *N. gonorrhoeae*.^{79,85,106,114,156,203,260} *N. gonorrhoeae* is well adapted to its human host and is able to co-opt components of the innate immune system for its survival. Species specificity is demonstrated by greater adherence of gonococci to human cells than to nonhuman cells. Close interactions of *N. gonorrhoeae* with mucosal cells, erythrocytes, spermatozoa, and polymorphonuclear cells are well described.

Gonococci are able to survive in the urethra in the face of hydrodynamic forces that tend to wash other microbes away and persist there despite close proximity and even attachment to the hordes of neutrophils that respond to their presence. These observations indicate an ability to adhere to mucosal epithelia and evade the host acute innate immune response. Individuals also can have repeated infections by the same gonococcal strain, suggesting that the organism can thwart establishment of local adaptive immune responses. The tissue damage that occurs in the fallopian tubes during salpingitis implies that one or more directly toxic moieties or factors can trigger a deleterious host response.^{116,305}

In the male human model of experimental infection, gonococci are recovered in urine at low levels for about 2 hours after urethral inoculation. The microbes then disappear from the urine for variable periods before becoming shed in increasing numbers. The bacteriuria persists until signs and symptoms of dysuria and urethritis appear after an incubation period of 1 to 6 days after inoculation. Severity of symptoms does not correlate with the shed microbial burden. Pyuria and detectable urinary concentrations of interleukin-6 (IL-6) and IL-8 usually appear within 24 hours after inoculation. Phenotypic variation of gonococcal surface determinants is seen during the course of experimental infection.¹⁵⁶

This human model and multiple *in vitro* molecular studies involving cell lines and fallopian tube organ cultures have provided many insights into the molecular pathogenesis of gonococcal infection.^{72,152,213,214,266}

Invasion of Mucosal Epithelial Cells

In addition to the ability to resist killing by neutrophils, gonococci are able to persist in human hosts via their ability to invade epithelial cells. The initial steps of intracellular invasion involve attachment of microbes to epithelial cell surfaces through synergistic effects of pili, Opa proteins, and porin proteins.^{18,85,137} Gonococci also exploit the production of complement factors, including C3, by cervical epithelial cells. In females, especially during the luteal phase and menses, C3 is secreted into the extracellular milieu, where it is activated to C3b. The gonococcal surface binds C3b and cleaves it to iC3b (inactive), which then serves as a ligand for the complement receptor 3 molecules on host cells that facilitates microbial attachment independently of pili and Opa proteins.¹⁰⁶

After adhering to host epithelial cells, some microbes are internalized by endocytosis triggered by interaction of gonococcal phospholipase D with host cell Akt (protein kinase B).¹⁰⁶ The vast majority of invading gonococci are ingested and killed by neutrophils. Gonococci are susceptible to the oxidative burst products of phagocytes, as well as to nonoxidative products such as cathepsin G.^{49,293} Those that survive

FIG. 89.4 Electron micrographs of *Neisseria gonorrhoeae* (strain MS11) interactions with polarized T84 human epithelial cell monolayers. At early stages of infection, the microbes adhere to the apical plasma membrane as microcolonies. (A) Adherent bacteria are surrounded by a matrix of microvilli. (B–C) Bacteria subsequently disperse from the microcolony and adhere as a monolayer in which bacterial and host-cell membranes are tightly apposed. (C) The region of contact between the bacteria and the host-cell membrane enlarges, with subsequent internalization of the microbes. (D) Bacteria then traverse the host cell and exit via the basolateral membrane. (From Merz AJ, So M. Interactions of pathogenic *Neisseriae* with epithelial cell membranes. *Annu Rev Cell Dev Biol.* 2000;16:423-457.)

intracellularly may replicate inside the phagosomes and ultimately exit the basal (but not lateral) surface of the cell via exocytosis^{214,219,234} (Fig. 89.4). Adjacent nonepithelial cells are sloughed, probably because of the toxicity of LOS and peptidoglycans.¹³⁵ Mucosal cell damage and submucosal invasion are followed by an influx of neutrophils along with the formation of submucosal microabscesses and exudation of purulent material into the lumen of the infected organ.³⁴¹

Adherence of gonococci to mucosal epithelial cells causes activation of nuclear factor- κ B (NF κ B) and activator protein 1, which in turn leads to upregulation and release of multiple cytokines and chemokines, including macrophage colony-stimulating factor, tumor necrosis factor- α (TNF- α), tumor growth factor- β (TGF- β), monocyte chemoattractant protein 1, IL-1 β , IL-6, and IL-8.^{235,259}

N. gonorrhoeae can form biofilms during cervical infection. Membrane blebs that contain DNA elements and outer membrane structures are key components of these biofilms. A gonococcal thermonuclease is involved in remodeling of biofilm matrix. Cells in the biofilm activate gene sets involved in anaerobic respiration.¹¹⁴

Resistance to Phagocytosis and Intracellular Killing

Subsets of infecting gonococci are able to resist extracellular killing by neutrophils through mechanisms that are increasingly understood. The microbes also resist phagocytosis via blocking deposition of opsonic antibodies and complement components on their own surfaces and by antigenic variation of their surface structures to evade any preexisting humoral immune responses. Antibody binding is inhibited by sialylation of surface lipo-oligosaccharide (LOS). Gonococci thwart the effects of complement via binding of the complement cascade inhibitor complement factor H to porin proteins and LOS.⁸⁵

N. gonorrhoeae have multiple mechanisms by which they resist oxidative and nonoxidative killing after phagocytosis by neutrophils. The species produces catalase, cytochrome *c* peroxidase, superoxide dismutase, and a metalloproteinase that detoxify superoxide compounds produced in phagolysosomes. Gonococci also have repair systems for oxidatively damaged DNA. Nonoxidative antibacterial factors such as lysozyme, elastase, cathepsin G, defensins, and cathelicidins can be counteracted by gonococcal efflux pump systems, metalloproteinase, and other protein and regulatory systems.⁸⁵

Neutrophil extracellular traps (NETs) form from chromatin and neutrophil granule components as neutrophils undergo programmed cell death in association with the oxidative burst in response to bacterial infection. Gonococci elicit NETs but may be able to degrade these with expression of the thermonuclease and also are able to suppress the oxidative burst process.^{142,178}

Specific Virulence Factors

Specific *N. gonorrhoeae* virulence factors include (1) pili, (2) opacity proteins, (3) porin protein, (4) the ability to survive in low iron environments, (5) immunoglobulin (Ig)A protease, (6) LOS, (7) cell wall peptidoglycan, (8) reduction modifiable protein (Rmp), and (9) a type IV secretion system. Many other gonococcal gene products and molecular systems have been identified, and a more detailed and complex understanding of virulence at the molecular level is steadily forthcoming.

Pili

Gonococci are piliated predominantly in vivo and express type IV pili. Pili cover essentially the entire surface of the cell and are arranged in individual fibrils or fibrillar aggregates. Pili consist primarily of polymers of an 18-kD subunit now denoted as PilE. A single pilus is approximately 6 nm in diameter and up to several microns in length.²¹⁹ Each may contain thousands of PilE subunits.⁴² The PilC protein is present in lower numbers in the pilus but appears to be the key pilus adhesin. PilC interacts with CD46 molecules, which are present on most human cells and serve as receptors for C3b, C4b, measles, and other viruses. PilC-CD46 attachment appears to be a key step in the initiation of microbial adherence to host cells.^{44,181,190,277,279}

Binding of pili to a host-cell membrane induces at least two responses in the host cell: release of Ca²⁺ from intracellular stores¹⁸⁰ and cytoskeletal rearrangements with the formation of cortical plaques that represent an accumulation of actin, ezrin, and other phosphotyrosine-containing proteins.^{217,263} The latter results in elongation of the microvilli that embrace the microbe. Formation of plaque appears to be induced by retraction of the attached pilus, and retraction depends on another pilus protein designated PilT.²²⁰

Gonococcal pili undergo both phase variation (switching from piliated to nonpiliated states) and high-frequency antigenic variation.⁴³ These

variations occur during natural infection and in vitro passage.²⁸⁹ Pili have a common N-terminal domain, semivariable domains in the midportion, and two hypervariable regions in the carboxyl-terminal of the pilin protein subunit.³⁰⁶ Relatively invariant regions occur between the variable domains. The pilin protein consists of 159 to 160 amino acids. The chromosome contains either one or two complete pilin genes. The expressed gene contains an intact promoter region, a ribosome binding site, and a seven-amino acid signal sequence in addition to the pilin sequence. Scattered around the chromosome are six to eight loci that contain varying portions of the pilin sequence without the promoter region or the 5' end of the structural gene. Some loci may contain many incomplete pilin sequences arranged head to tail that differ slightly from one another. Movement of these sequences into the active expression site through nonreciprocal combination events results in antigenic variation of the pilus protein. If recombination leads to a faulty pilin subunit product that cannot be processed into a mature pilus, the progeny of that organism become nonpiliated (phase variation). Subsequent recombination events can allow reversion back to the pilated phase.^{145,221,222,239,288,306,319}

In addition to promoting adhesion to epithelial cells, pili also provide a twitching motility, are involved in DNA transformation, and may play a role in resistance to ingestion by phagocytic cells.²²⁸ The presence of pili, perhaps mediated through their promotion of adhesion, affects the activation of CD4⁺ T-lymphocytes and the production of IL-10. This property may help gonococci diminish the T-cell response to their presence.²⁵³

Opacity-Associated Proteins

Opa proteins also influence adherence of the gonococcus to host cells. The isolation of particular Opa protein phenotypes from different anatomic sites or at different times during the menstrual cycle has suggested that these proteins contribute to the ability of the organism to succeed in a given niche. Opa proteins (formerly designated protein II) are a set of as many as 12 related proteins that are variably present in gonococcal outer membranes. Opa proteins are 24 to 28 kDa in size and confer increased opacity to colonies of organisms by promoting adherence of the organisms to one another. A given strain has the capacity to make at least 10 different Opa proteins but appears to express no more than five at the same time. Some cells express no Opa proteins. Like pili, Opa proteins undergo both antigenic and phase variation. Both types of variations can occur within a single colony, so sector variations in opacity can be seen.^{27,305,317,318}

Each *opa* gene is present as a complete gene with its own promoter and is transcribed at all times. Phase variation in expression occurs at the translational level. Each gene has a varying number of pentameric CTCTT repeat units adjacent to the ATG start codon. When the number of repeats is divisible by three, the transcribed mRNA is translationally in frame and the Opa protein is expressed. The number of pentameric repeats is subject to high-frequency variation. Antigenic variation results from recombination between the two hypervariable regions in each of the *opa* genes.^{75,308–320}

Two classes of host-cell receptors for Opa proteins have been identified. Heparan sulfate–proteoglycan (HSPG) receptors are present on epithelial cells and interact with one particular Opa protein variant (Opa₅₀). HSPG binding can stimulate the lipid hydrolysis enzymes phosphatidylcholine-specific phospholipase C and acid sphingomyelinase and thereby lead to clathrin-independent endocytosis. HSPG–Opa binding also can lead to interactions with serum factors such as vitronectin and fibronectin, which then mediate endocytosis via host-cell integrin receptors. The CD66 family is present on epithelial cells and neutrophils, recognizes many different Opa proteins, and mediates nonopsonic phagocytosis, a process distinct from antibody- and complement-mediated phagocytosis.^{92,91,134,193,218,219,330}

Porin Protein

Formerly designated protein I, porin protein is the most common gonococcal outer-membrane protein. Porin is 34 to 36 kDa, is exposed on the surface, exists as a trimer in the membrane, and is physically proximate to LOS and Rmp.^{28,155} The trimer forms an anion-specific pore in the bacterial membrane that allows small water-soluble molecules

to enter the cell.³⁴⁴ The *por* locus has two alleles that encode chemically and immunologically distinct classes of porin protein—PorA and PorB—that are similar to porin proteins in other gram-negative bacteria. A given strain expresses only PorA or PorB, and many antigenic variants of both exist (thereby forming the basis for serotyping).^{48,188}

The porin trimer appears to translocate into the host-cell membrane and is able to disrupt neutrophil degranulation, the oxidative burst, and phagosome maturation,^{146,205,227} in addition to induction of apoptosis in epithelial cells and neutrophils in vitro.²³¹ Exposure to gonococcal porin protein induces the typical structural and biochemical changes seen in apoptotic cells.²³⁰ Porin translocation permits rapid influx of Ca²⁺ into the host cell from the external environment.²³¹ Porin proteins also may play a role in endocytosis mediated by the binding of HSPG and Opa protein¹⁸ and in downregulation of complement by binding with C4b-binding protein.²⁵⁸

Iron Metabolism

Iron is an essential nutrient for *N. gonorrhoeae*, and, in host tissues, iron is sequestered in hemin compounds as ferritin or is bound to lactoferrin or transferrin. The species does not produce any siderophores but relies on an iron-repressible system that scavenges iron from transferrin, lactoferrin, and hemoglobin. This system comprises numerous proteins, some of which serve as receptors for the aforementioned iron-bearing ligands.^{25,69,80,335} Other components include a TonB-dependent transporter and an associated lipoprotein that are expressed ubiquitously by gonococci, have limited antigenic variability, and are important for growth in vivo.⁷⁹ These proteins thus have potential as vaccine targets.

Immunoglobulin A Protease

All gonococci (and meningococci, but not nonpathogenic *Neisseria* spp.) make a protease that cleaves both serum and secretory IgA1 (but not IgA2) at the hinge region with the release of Fab and Fc fragments. This protease may help the organism evade host IgA at the mucosal surface, especially early in secondary infections, when preexisting antibodies may be present. However, mutant strains without the IgA protease have limited ability to grow inside epithelial cells. The protease appears to cleave a host-cell intracellular protein (LAMP1) involved in phagosome compartmentalization.¹⁹⁹ IgA1 protease is not required for gonococci to cause experimental urethritis,¹⁷³ thus suggesting that its intraphagosome function may be more important in pathogenesis.

Lipo-Oligosaccharide

Gonococci express LOS complexes of 3 to 7 kDa on their cell surface. LOS consists of a lipid A moiety and a core polysaccharide comprising ketodeoxyoctanoic acid, heptose, glucose, galactose, glucosamine, galactosamine, or any combination of these constituents.¹³⁹ The lack of a long polymeric sugar attached to the core distinguishes LOS from the lipopolysaccharides of other gram-negative bacteria. The core sugar antigens of LOS are subject to intrastrain and interstrain variation, and a single strain may express as many as six variants of LOS.^{94,138} Numerous genes are involved in LOS synthesis; these genes undergo high-frequency phase variation similar to *opa* genes.¹³³ LOS terminal sugars mimic the structure of certain human glycosphingolipids.¹³⁹

Gonococci with predominately short LOS molecules appear to be more sensitive to killing by human serum but also more able to invade eukaryotic cells. Strains with longer LOS are more serum-resistant but noninvasive.³³¹ Longer LOS moieties are sialylated readily with host neuraminic acid by a bacterial sialyltransferase that appears to shield both LOS and porin molecules from antibody binding, thus providing protection from complement-mediated killing in serum.^{32,336}

LOS from serum-sensitive strains is able to activate the classic complement pathway and may do so in the absence of antibody.²⁹² LOS induces the production of cytokines (i.e., TNF- α , IL-1 β , IL-6, and IL-8) by urethral epithelial cells¹⁴⁸ and can mediate host defensin-enhanced adherence to epithelial cells.¹³²

Cell Wall Peptidoglycan and Lytic Transglycosylases

Gonococci shed membrane fragments with peptidoglycan into their environment during exponential growth. Peptidoglycan monomers have

numerous biologic properties, including activation of complement and modulation of mononuclear cell proliferation. These fragments also damage fallopian tube mucosa in organ culture, thus suggesting a pathogenic role for the compounds in invasive disease.^{135,214} Production of peptidoglycan monomers is a by-product of lytic transglycosylases that act during cell growth and division. At least five such enzymes are encoded by *N. gonorrhoeae*. These also may facilitate gene transfers as part of type IV secretion.⁶⁵

Reduction Modifiable Protein

Rmp (formerly designated protein III) is an antigenically conserved, 30- to 31-kDa protein that is present in all pathogenic *Neisseria*. Rmp is located proximate to LOS and porin in the outer membrane. Antibodies that bind to Rmp epitopes block the bactericidal effect of the complement-fixing IgM antibodies that recognize LOS. Women with preexisting anti-Rmp antibodies appear to be more susceptible to the development of infection than do those without such antibodies.^{268,269,305}

Ribosomal Protein L12

Ribosomal protein L12 mimics the structure of human chorionic gonadotropin, the natural ligand for lutropin receptors. It is able to bind to lutropin receptors in the upper female genital tract, which may facilitate ascending infection in females.^{104,309}

Type IV Secretion System

About 80% of *N. gonorrhoeae* strains encode a horizontally acquired 57-kb genetic island that encodes a type IV secretion system (T4SS). A T4SS is a multiprotein complex that functions as a conjugation system. In gonococci the T4SS secretes single-stranded chromosomal DNA into the extracellular environment. T4SS expression may enhance microbial survival inside human cells in addition to its role in genetic recombination and natural transformation among gonococcal strains.²⁶⁰

Characteristics of Strains Causing Disseminated Disease

The increased virulence of some strains is suggested by observations such as a microepidemic of gonorrhea involving one asymptomatic infected male and eight female contacts.¹⁴⁹ Seven of the women were infected symptomatically, and four experienced disseminated infection. Overall many infections are asymptomatic and dissemination is relatively rare.

Strains of *N. gonorrhoeae* obtained from adult patients with disseminated disease usually are less susceptible to the bactericidal activity of sera.^{38,73,266,267,294} These strains have an atypical growth pattern on agar²²⁴ that reflects the absence of Opa protein expression, which suggests that the genetic variation capacity described earlier allows adaptation to different niches and probably helps organisms elude the host response.²² Unlike most gonococcal strains, many invasive strains (designated AHU⁻) require arginine, uracil, and hypoxanthine for growth.¹⁸⁶ A high degree of sensitivity to penicillin also has been characteristic of most strains from patients with disseminated disease.³⁴⁰ Many also are susceptible to vancomycin, which may prevent detection in selective media. These strains should be detected in the usual media used for blood culture.

Host Response

The adult response to local and systemic infection with *N. gonorrhoeae* has been investigated extensively, but no such studies have been performed on infected children. Gonococcal infections usually are characterized by intense inflammation that involves neutrophilic and mononuclear granulocytes. The vast majority of gonococcal cells ingested by neutrophils are killed.⁴⁹ Gonococci are susceptible to the oxidative products produced by neutrophils but also can be killed efficiently by nonoxidative products such as cathepsin G.²⁹³

An intact complement system is essential for successful eradication of the organism. Properdin-mediated recruitment of C4b-binding protein facilitates antibody-mediated complement-dependent killing of gonococci that resist destruction via the classic complement pathway.¹⁴¹ Persons with inherited or acquired complement deficiencies may be predisposed to contracting disseminated gonococcal infection, as is the case with meningococcal infection. Approximately 13% of patients with disseminated disease have complement deficiencies.^{109,242}

Adherence of gonococci in vitro induces the activation of NFκB and activator protein 1, which leads to upregulation of messenger RNA (mRNA) and release of numerous cytokines and chemokines: macrophage colony-stimulating factor, TNF-α, TNF-β, monocyte chemoattractant protein 1, IL-1β, IL-6, and IL-8.²³⁵ Intraurethral challenge leads to increased levels of IL-8, IL-6, and TNF-α in urine before the onset of symptoms and in plasma at the onset of symptoms.²⁵⁹
